Foreword

The Journal of Physical and Chemical Reference Data is published jointly by the American Institute of Physics and the American Chemical Society for the National Institute of Standards and Technology. Its objective is to provide critically evaluated physical and chemical property data, fully documented as to the original sources and the criteria used for evaluation. One of the principal sources of material for the journal is the National Standard Reference Data System (NSRDS), a program coordinated by NIST for the purpose of promoting the compilation and critical evaluation of property data.

The regular issues of the Journal of Physical and Chemical Reference Data are published bimonthly and contain compilations and critical data reviews of moderate length. Longer works, volumes of collected tables, and other material unsuited to a periodical format have previously been published as Supplements to the Journal. In 1989 the generic title of these works was changed to Monograph, reflecting their character as independent publications.

This volume, the Fourth Edition of the NIST-JANAF Thermochemical Tables, is Monograph No. 9 in the current series. Its predecessor, the Third Edition, was referred to as a Supplement. Of the over 500 titles published in the last 25 years, the articles dealing with the JANAF Thermochemical Tables have been the most widely distributed and used.

The Journal of Physical and Chemical Reference Data is therefore pleased to be able to publish this Fourth Edition of the NIST-JANAF Thermochemical Tables. There are two important features of this edition. First, the acronym NIST has been added to the title of this activity. This is due to the fact that during the past 10 years, NIST has been the leading financial supporter for this effort. Additionally, this project is now housed within the Physical and Chemical Properties Division at NIST. Second, the Fourth Edition contains additional species not included in the Third Edition. A number of typographical errors have also been corrected.

Malcolm W. Chase, Jr., Editor
Journal of Physical and Chemical Reference Data

Preface to the First Edition

Beginning in the mid-1950s, when elements other that the conventional carbon, hydrogen, oxygen, nitrogen, chlorine, and fluorine came into consideration as rocket propellant ingredients, formidable difficulties were encountered in conducting rigorous theoretical performance calculations for these new propellants. The first major problem was the calculational technique. The second was the lack of accurate thermodynamic data.

By the end of 1959, the calculational technique problem had been substantially resolved by applying the method of minimization of free energy to large, high speed digital computers. At this point the calculations became as accurate as the thermodynamic data upon which they were based. However, serious gaps were present in the available data. For propellant ingredients, only the standard heat of formation is required to conduct a performance calculation. However, this must be known to a high degree of accuracy. For combustion products, the enthalpy and entropy must be known, as a function of temperature, in addition to the standard heat of formation.

In order to resolve the problem, a substantial experimental thermodynamic research program was initiated under the sponsorship and technical direction of Project PRINCIPIA of the Advanced Research Projects Agency. Simultaneously, a project was initiated to critically evaluate and compile consistent tables of thermodynamic properties of propellant combustion products for use by the aerospace industry. This project, known as the JANAF Thermochemical Tables, was undertaken by the Dow Chemical Company. Since the objective of the project was to have one single source of best available data prepared for use by the entire industry, the JANAF Thermochemical Panel undertook the task of furnishing a critical review of the Tables prior to their publication and distribution. This approach was designed to ensure that the Tables be of the highest possible quality.

C. V. Mock
Advance Research Projects Agency

Preface to the Second Edition

It is appropriate to call attention to some of the reasons for the phenomenal success of the JANAF Thermochemical Tables in achieving, first, the initial limited objective of providing the standard data for the chemical rocket propulsion industry, and later, upon publication, worldwide recognition as thermodynamic reference data of the highest quality and timeliness.

First, and most obvious, there was the selection and continued support of a highly competent evaluation team, themselves engaged in a broad spectrum of thermodynamic research. The personnel of the Thermal Research Laboratory of the Dow Chemical Company, under the direction of Dr. D. R. Stull and Dr. H. Prophet, have filled this role to a degree of excellence not likely to be exceeded anywhere. Moreover, the group has heroically remained productive in spite of many battles to retain continuing support, and the actual sharp reduction of funding over the past two years to a less-than-viable level.

A second important factor is the unusual approach to format, evaluation, and distribution of the Tables, as it has been followed since their inception. The primary distribution is in frequently issued loose-leaf supplements. Each previously issued table may thus be revised as often as necessary to take account of improved data. Each loose-leaf table is accompanied on its reverse side by a complete explanation of the selection of the key data, together with all references.

The third vital distinction of these tables has been the existence of a continuing cognizant working group composed of technological users of data, thermodynamicists, and government sponsors of both research and development. Independent prepublication review of the Tables has been an important contribution of some of the members of this group; but its annual technical meetings have resulted in even more far-reaching benefits. Together, the users and generators of data have been able to establish realistic priorities for the species to be included in the Tables; at the same time the course of experimental research has been guided by the demonstration of absence or inadequacy of needed data. Although the working group no longer enjoys official recognition, the members and participants have enthusiastically volunteered to continue meeting in this important work.

Special words of appreciation are due to Dr. Charles W. Beckett, who has lined up all the technical presentations at the last six annual meetings of the working group; and to Mr. Curtis C. Selph who has served with wisdom and insight as the Air Force project monitor for the JANAF Thermochemical Tables contracts.

Joseph F. Masi
Air Force Office of Scientifc Research

Preface to the Third Edition

The United States Air Force (USAF) for more than 20 years has supported, and continues to support, the preparation of the JANAF Thermochemical Tables. The Tables, funded through Air Force Office of Scientific Research (AFOSR), were intended originally for calculating performance of thermochemical reactors, such as rocket engines. The computation of such performance figures as thrust and exhaust temperature for a rocket require data such as those in these tables.

The Department of Energy (DOE) [and predecessor agencies Energy Research and Development Administration (ERDA), Office of Coal Research, and Bureau of Mines] became interested in the JANAF Thermochemical Tables because the tables had become *the* benchmark for thermochemical data for performance calculations. However, reactors and reagents of interest to DOE are different from those of the USAF.

The Department of Energy needs performance calculations for several types of reactors that are of interest in fossil fuel research. These reactors include air pollution control equipment, automotive internal combustion engines, coal gasifiers and furnaces, fuel cells, liquefaction reactors and their catalyst structures, and magnetohydrodynamic generators. For example, researchers might wish to calculate the first-law efficiency of an electrical power plant, or the exhaust concentration of a pollutant such as sulfur dioxide or mercury.

The calculations needed for DOE interests have as their basis the same mathematics and physical chemistry as required for the performance calculations of USAF interest, but DOE needs tables for more and different chemicals. For example, a rocket fuel probably would not be formulated to include silicon or sulfur, but all known coals contain both these elements. Silicon and sulfur are two distinguishing elements accounting for many peculiarities of coal utilization chemistry (which include the chemistries of all the polysulfides, thiosulfates, alums, etc., and of the many glasses and mixed silicates).

For more than six years (1975-1982), Dow Chemical has worked on separate but complementary contracts to satisfy the thermochemical tables' needs of USAF and DOE. This Third Edition of the JANAF Thermochemical Tables presents the results of these efforts, along with reformatted versions of previous tables, to provide an extensive set of tables of wide utility that are consistent with each other and with the requirements of thermodynamic theory.

There remain open questions about calculation methods for equilibrium problems. I mention this because the foreword for the First Edition endorses free-energy-minimization as if it solved all problems of numerical instability. I would remove this apparent endorsement as confusing, inappropriate, and uninformative for users of these tables. For example, the paper of White, Johnson, and Dantzig [J. Phys. Chem. 28, 751 (1958)] does not address numeric stability in any way. Removing this endorsement would not diminish Dow's JANAF work.

I want to thank several people. All the Dow personnel did outstanding work, and several fellow federal employees helped with orchestrating the various contracts to nourish this finished product. In AFOSR, Joseph Masi, Robert Sperlein, and Leonard Caveny were always encouraging. Within the Bureau of Mines, then in ERDA, and finally in DOE, I was helped and encouraged by Daniel Bienstock, Irving Wender, Jim Hendrie, Alex Mills, Kermit Woodcock, and Mike Hogan.

Preface to the Fourth Edition

As the Standard Reference Data Program at the National Institute of Standards and Technology approaches its thirtieth year, the release of the fourth edition of the NIST-JANAF Thermochemical Tables provides not only a major update to this important reference work, but also a symbol of the long-term dedication of NIST and its scientists to improving the quality and accessibility of scientific data.

First, let us address the importance of the NIST-JANAF Thermochemical Tables. This fourth edition continues to serve its original community, that is, the scientists and engineers who design rocket propellants. For this use, the updated tables offer additional species and in some cases, corrected data for older species. The use of the NIST-JANAF Thermochemical Tables, however, now far transcends the original need. Today, as modeling of complex chemical processes is becoming routine, NIST-JANAF information is an invaluable resource for reliable thermochemical data. Care of preparation and critical evaluation still form the essence of the compilation. New users are demanding new species, and the tables are being responsive to those demands. There is no other comprehensive source of temperature dependent thermochemical data for inorganic species, certainly none of such high quality.

From another perspective, this edition is an important milestone, for this publication again demonstrates the long-term commitment by NIST to providing evaluated scientific and technical data through its Standard Reference Data Program. Established by the Standard Reference Data Act of 1968, the program today operates data evaluation activities in most areas of NIST's scientific and engineering work.

The Physical and Chemical Properties Division of the NIST Chemical Science and Technology Laboratory (and its predecessors) has for many decades been committed to providing critically evaluated thermochemical data. The "International Critical Tables," "The NIST Tables of Chemical Thermodynamic Properties; Selected Values for Inorganic and C_1 and C_2 Organic Substances in SI Units," and now the "NIST-JANAF Thermochemical Tables" are prime examples of the fruit of this commitment.

The scientific effort required to produce critically evaluated data is difficult for the non-specialist to appreciate. Even though many thermochemical, experimental, and theoretical techniques are well-developed, rarely does one individual measurement or calculation provide "property data." Instead most properties of substances come from repeated measurements, done over time and by different groups, and it is the job of the data evaluator to reconcile conflicting information and extract standard reference data of the type presented in the NIST-JANAF Thermochemical Tables. Malcolm W. Chase was the responsible scientist for the third and fourth editions, and the high quality of data contained in this latest edition is a tribute to his experience and skills as an evaluator.

Finally, it should be noted that the change of name to the NIST-JANAF Thermochemical Tables is the result of greater involvement by NIST in supporting the new edition. Data work at NIST is a team effort, in this case, of the Physical and Chemical Properties Division and the Standard Reference Data Program. The NIST-JANAF Thermochemical Tables represent a renewed dedication on the part of both organizations to make sure that scientists and engineers in industry, government, and academe have access to numeric recommendations of known reliability, for use in research, development, and related technical activities. NIST is proud to present this data compilation to the technical community.

The Table of Contents is a cumulative listing of Parts I and II.
Part I contains pp. I–XI and 1–957 (Tables for Al-Co), and
Part II contains pp. 959–1951 (Tables for Cr-Zr).

1. Introduction

The Fourth Edition to the NIST-JANAF Thermochemical Tables has been assembled under the sponsorship of the Standard Reference Data Program at the National Institute of Standards and Technology. It contains tables of recommended temperature-dependent values for the standard enthalpy of formation, Gibbs (free) energy of formation, the logarithm of the equilibrium constant of formation, the heat capacity, entropy, enthalpy, and Gibbs energy function for 48 elements and many of their compounds. This publication is a current collection of all tables issued through 1997 under contracts with the U.S. Department of Energy and the U.S. Air Force Office of Scientific Research, NASA, the JANNAF Combustion Subcommittee, and the Standard Reference Data Program. It supersedes the Third Edition,[1] which, in turn, superseded the Second Edition,[2] and the four supplemental updates published in the Journal of Physical and Chemical Reference Data.[3–6]

Numerous new and revised thermochemical tables are included in this collection. [Refer to Sec. 7] Unlike the Third Edition of these tables, the Fourth Edition is not a rewriting and a recalculation of all the tables; no attempt has been made to reanalyze the data for all tables. A continued effort was made to correct all typographical errors from previous publications and to force an increasingly consistent style and format. The tables adhere more closely to the current IUPAC recommendations on symbols and notation. The tables, as published in the previous Third Edition, are all based on the 1981 IUPAC[7a] and 1973 CODATA[8a] recommendations for relative molecular masses and fundamental constants. As a result, a comparison of a table in the Fourth and Third Editions and their previously published form (i.e., same revision date) will reveal differences; however, these result from the adjustments mentioned above rather than from a reanalysis of the data. For tables issued since the Third Edition, values of the fundamental constants and relative molecular masses are based on the 1993 IUPAC[7b] and 1986 CODATA[8b] recommendations. It should be noted that there is a revised set of recommendations for the fundamental constants due in late 1998. Also, it should be remembered that the relative molecular masses are reassessed and updated every two years. The effects of these changes will be discussed later.

All thermal functions have been calculated using the same auxiliary data. Following a similar procedure for the formation properties has introduced slight inconsistencies in those tables for which the formation properties were derived from the previous thermal functions.

2. History of the JANAF Thermochemical Tables

Between 1955 and 1958, severe difficulties were encountered by individuals attempting to conduct rigorous performance calculations for propellant systems that gave multiphase combustion products characterized by complex chemical and thermal equilibria. Several of these individuals approached the Armed Services requesting that a group be assembled to assess the validity of the calculation methods and thermochemical data which were being employed at that time.

January 1958, the Armed Services jointly instructed the Solid Propellant Information Agency to organize the Joint Army-Navy-Air Force Ad Hoc Panel on Performance Calculation Methods and Thermodynamic Data. This panel, which consisted of 38 representatives of military facilities, defense contractors, and research organizations, terminated its operations in June 1959, with a recommendation that future activities under its purview could more appropriately be handled by a smaller working group. An additional recommendation included in the panel's final report was that this working group initiate the establishment of a thermochemical data compilation, evaluation, and dissemination program utilizing the available personnel and facilities of the Dow Chemical Company.

On 1 September 1959, the Joint Army-Navy-Air Force Thermochemical Panel was formed under the sponsorship of the Bureau of Naval Weapons, Department of the Navy; Office, Chief of Ordnance, Department of the Army; Air Research and Development Command, Department of the Air Force; and the Advanced Research Projects Agency, Department of Defense. The panel operated in accordance with the Rules of Operations of Solid Propellant Panels as adopted by representatives of the above offices on 1 September 1959.

The JANAF Thermochemical Panel Membership, which consisted originally of approximately 15 individuals with special experience in the technological subject under panel purview, met at the Pentagon on 16 November 1959, at which time plans for the thermochemical compilation project were reviewed and the project formally initiated.

Urgency required that a large set of consistent tables be assembled as quickly as possible. Computer programs had to be developed, and at first it was not possible to adequately assess the input information for every table. When the original data were evaluated, the table was printed on white paper; otherwise, the table was printed on gray paper. By the end of 1960, the first set was ready for distribution to some 1000 qualified recipients. For a number of years, at the end of each quarter, a supplement was issued which contained additional tables and revised tables. Some of the gray tables were revised to white tables.

The distribution of quarterly supplements continued through 31 December 1967, at which time the distribution shifted to semiannual supplements. Simultaneously, the tables were prepared under the auspices of the Interagency Chemical Rocket Propulsion Group, Working Group on Thermochemistry. On 31 December 1970, the working group became the Ad Hoc Working Group on Thermochemistry. By 30 June 1971, the tables project was sponsored by the U. S. Air Force Office of Scientific Research (AFOSR) and prepared under the advice and assistance of a thermochemistry group, referred to as reviewers. In late 1976, the U.S. Energy Research and Development Administration (now reorganized to be the U.S. Department of Energy) joined in sponsoring the tables.

The distribution reverted to a quarterly schedule with an expanded list of reviewers. AFOSR and DOE jointly funded this activity until late 1982. AFOSR continued as the sole sponsor until 1986.

From 1967 through 1985, the JANAF Thermochemical Tables have been sponsored by the U.S. Air Force Office of Scientific Research and the U.S. Department of Energy under the following contracts:

Air Force Contracts	Department of Energy Contracts
F04611-67-C-0009	DE AC22-76ET10637
F04611-70-C-0028	DE AC22-81PC41514
F44620-70-C-0104	
F44620-75-C-0048	
F49620-82-C-0016	

In addition, there was an interagency transfer of funds, from AFOSR to DOE, in the period 1976-1981.

In 1970 the output of the JANAF project was incorporated into the National Standard Reference Data System, a national program on evaluated physical and chemical data which is coordinated by the National Institute of Standards and Technology. Since that time the JANAF Thermochemical Tables have been disseminated as part of the Journal of Physical and Chemical Reference Data. Loose-leaf supplements were terminated with the publication of the Third Edition.

In January 1986, the JANAF Thermochemical Tables project transferred from the Dow Chemical Company to the National Institute of Standards and Technology. Funding since 1986 has come in large part from the Standard Reference Data Program, with additional contracts with NASA, JANNAF Combustion Subcommittee, and the U. S. Army. Updates to this Fourth Edition are being made in separate articles, many of which (but not all) are to be published in the Journal of Physical and Chemical Reference Data.

2.1. Members of the JANAF Thermochemical Panel (1959-1961) and the JANAF Thermochemical Working Group (1961-1964)

T. O. Dobbins, Advanced Research Projects Agency (Past Chairman)

W. H. Jones, Institute for Defense Analyses; Aerospace Corporation (Past Chairman)

W. G. May, Institute for Defense Analyses; Esso Research and Engineering Company (Past Chairman)

C. W. Beckett, National Bureau of Standards (Vice Chairman)

G. W. Avery, Chemical Propulsion Information Agency (Past Secretary)

B. K. Farris, Chemical Propulsion Information Agency (Past Secretary)

T. L. Reedy, Chemical Propulsion Information Agency (Secretary)

B. J. Alley, Army Materiel Command

P. W. Bender, University of Wisconsin

W. A. Bernett, Bureau of Naval Weapons

B. Brown, Hercules Powder Company

C. L. Funk, Jet Propulsion Laboratory

J. S. Gordon, Thiokol Chemical Corporation

L. J. Gordon, Aerojet-General Corporation

S. A. Greene, North American Aviation

C. B. Henderson, Atlantic Research Corporation

D. L. Hildenbrand, Philco Corporation

J. L. Margrave, University of Wisconsin

J. P. McCullough, U.S. Bureau of Mines

P. L. Nichols, Jr., Jet Propulsion Laboratory

C. C. Selph, Air Force Systems Command

D. R. Stull, Dow Chemical Company

The Thermochemical Working Group of the Interagency Chemical Rocket Propulsion Group (ICRPG) has consisted of the following at various times during its existence (1964-1969).

Members

J. F. Masi, Air Force Office of Scientific Research (Chairman)

C. W. Beckett, National Bureau of Standards (Vice Chairman)

T. O. Dobbins, Advanced Research Projects Agency

S. Gordon, National Aeronautics and Space Administration

R. Jackel, Office of Naval Research

J. Murrin, Naval Ordnance Systems Command

R. Odom, Army Materiel Command

C. C. Selph, Air Force Rocket Propulsion Laboratory

D. Squire, Army Research Office

Participants

G. S. Bahn, Marquardt Corporation

B. Brown, Hercules, Inc.

H. F. Calcote, AeroChem Research Laboratories

J. P. Coughlin, Aerojet-General Corporation

J. S. Gordon, Atlantic Research Corporation

D. R. Douslin, U.S. Bureau of Mines

M. Farber, Space Sciences, Inc.

R. M. Fristrom, Applied Physics Laboratory

C. B. Henderson, Atlantic Research Corporation

D. L. Hildenbrand, Douglas Aircraft Company

J. L. Margrave, Rice University

W. G. May, Esso Research and Engineering Company

W. Mitchell, Thiokol Chemical Corporation

C. F. Robillard, Jet Propulsion Laboratory

L. Schieler, Aerospace Corporation

C. H. Shomate, Naval Weapons Center

D. R. Stull, Dow Chemical Company

M. Zimmer, Naval Ordnance Station

Secretariat (Chemical Propulsion Information Agency)

T. Gilliland

M. McCormack

T. L. Reedy

In the period 1969-1984, various scientists donated their time to critique the loose-leaf supplements to the JANAF

Thermochemical Tables prior to their distribution. Their efforts certainly increased the quality of the tables. As of January 1982 the reviewers of the JANAF Thermochemical Tables were:

DOE Reviewers

Francis E. Spencer, Jr., DOE/PETC Combustion Technical Division

Joseph W. Martin, DOE/METC, Coal Projects Management Division

Thomas C. Ehlert, Marquette University

R. Howald, Montana State University

Fred C. Fehsenfeld, NOAA Environmental Research Laboratory

Gerd Rosenblatt, Los Alamos National Laboratory

Martin Steinberg, University of California, Santa Barbara

C. B. Alcock, University of Toronto

J. Brian Pedley, University of Sussex

Malcolm H. Rand, AERE Harwell.

AFOSR Reviewers

David White, University of Pennsylvania

W. L. Worrell, University of Pennsylvania

Stanley Abramowitz, U.S. National Bureau of Standards

David A. Ditmars, U.S. National Bureau of Standards

H. M. Rosenstock, U.S. National Bureau of Standards

Leonard Caveny, AFOSR/NA, Bolling AFB

John L. Haas, Jr., U.S. Geological Survey

John S. Gordon, TRW Energy Systems

Joseph F. Masi, AFOSR (retired)

Sanford Gordon, NASA Lewis Research Center

Edgar F. Westrum, Jr., University of Michigan

William D. Good, DOE/BETC

R. H. Hauge, Rice University

John L. Margrave, Rice University

Milton Farber, Space Sciences, Inc.

Curtis C. Selph, AFRPL/LKDH

Donald L. Hildenbrand, SRI International

Leo Brewer, University of California

James P. Coughlin, Aerojet Tactical Systems Co.

N. A. Gokcen, U.S. Bureau of Mines, AMRC

2.2. Project Personnel

The Tables began under the direction of Daniel R. Stull in 1959. Major contributions in the first two years were made by Thomas E. Dergazarian, Samuel Levine, and Louis A. DuPlessis. In 1969 Harold Prophet succeeded Daniel R. Stull as project director and continued in that position until his untimely death in late 1972. Malcolm W. Chase has been project director since late 1972.

The following professional personnel of the Dow Chemical Company have been involved in the preparation of the JANAF Thermochemical Tables:

Project Director, D. R. Stull	1959-1969
Project Director, H. Prophet	1969-1972
Project Director, M. W. Chase	1972-1985
P. A. Andreozzi	1980-83
J. Chao	1961-69
J. L. Curnutt	1969-79
T. E. Dergazarian	1959-63
C. A. Davies	1980-85
J. R. Downey, Jr.	1976-85
L. A. DuPlessis	1960-61
D. J. Frurip	1983-85
S. T. Hadden	1962
A. T. Hu	1965-70
B. H. Justice	1964
G. C. Karris	1965-68
S. Levine	1960-61
R. A. McDonald	1971-85
F. L. Oetting	1961
R. S. Orehotsky	1963-64
R. V. Petrella	1961-62
E. W. Phillips	1963-66
J. A. Rizos	1962-63
G. C. Sinke	1962,65,69,70
A. C. Swanson	1962-64
A. N. Syverud	1963-84
H. K. Unger	1963-64
E. A. Valenzuela	1975-81
L. C. Walker	1971-73
D. U. Webb	1967-68
S. K. Wollert	1963-65

We also wish to mention the valuable assistance in the typing of these Tables of Norma Dumont, 1959-64; Viola E. Harrington, 1964-66; Carol S. Scheffier, 1966-67; Wildene B. Harris, 1967-68; Mary J. Walter, 1968-71; and for the time period of 1971-78 of Joan Weldon, Cheri Snow, Barbara Boman, Sheila Knoerr, Patricia Grochowski, and Lisa Ittner. For the years 1978–1985 Betty Clark, Jan Crouch, and Rhoda Toth have typed the tables. Isabel Carr provided valuable services to the group in abstracting, searching and ordering documents, and proofreading the Tables for the Second Edition. For the period 1978–1985 Dana Donley, Debbie Simpson, Marge Sheets, Barbara Meier, Diana Scribner, and Anne Schmidt have provided similar assistance. Milton D. Marks was very instrumental in all computer aspects of this project in the 1980's.

In the time period of 1985 to 1998, technical contributions have been made by Stanley Abramowitz and David Neumann. Additional help in literature searching, data collection, and data entry has been provided by Cindy Jackson, Rhoda Levin, and Sabina Crisen.

3. Notation and Terminology

The symbols and terminology for physicochemical quantities and units are those recommended by IUPAC through its Physical Chemistry Division.[9,10] For the thermodynamic notation needed but not specified by these two sources, the recom-

mendations of the Bulletin of Chemical Thermodynamics[11] are used. Similarly, for spectroscopic nomenclature, the common practice of Moore[12] and Herzberg[13–16] is followed.

3.1. Definition of the Standard State

This description of the standard state is an abbreviated version of that given by the IUPAC Physical Chemistry Division.[10]

Absolute values of some thermodynamic quantities are unknown. Only changes in values caused by changes in parameters such as temperature and pressure can be determined. It is therefore important to define a base line for substances, to which the effect of such variations may be referred. The standard state is such a base line. The properties of these standard states are indicated by use of the symbol°. For a pure substance the concept of standard state applies to the substance in a well-defined state of aggregation at a well-defined but arbitrarily chosen standard pressure.

Historically, the defined pressure for the standard state, i.e., the standard-state pressure, had been one standard atmosphere (101 325 Pa). With the growing use of SI units, continued use of the atmosphere is inconvenient. IUPAC has recommended that the thermodynamic data should be reported for a defined standard-state pressure of 100 000 Pa. The standard-state pressure in general is symbolized as $p°$. Previously all JANAF thermochemical publications prior to the Third Edition, $p°$ was taken as 1 atm. Beginning with the Third Edition of the JANAF Thermochemical Tables, $p°$ is taken as 100 000 Pa (1 bar). It should be understood that the present change in the standard-state pressure carries no implication for "standard pressures" used in other contexts, e.g., the convention that "normal boiling points" refer to a pressure of 101 325 Pa (1 atm).

The change of the customary value of $p°$ from 1 atm (101 325 Pa) to 1 bar (100 000 Pa) results in small alterations in standard values of some thermodynamic quantities for all substances. For condensed phases the magnitude of these alterations is nearly always negligible in comparison with the uncertainty of current data. However, the alterations in values of entropy and the Gibbs energy function for a pure gaseous substance and of the Gibbs energy of reaction for a reaction involving gaseous species may not be negligible. This will be discussed in detail later (Sec. 4.3).

Hence, in all the tables appearing in this publication the standard state for a pure gaseous substance is that of the substance as an (hypothetical) ideal gas at 1 bar; the standard state for a pure liquid substance is that of the pure liquid under a pressure of 1 bar; the standard state for a pure solid substance is that of the pure crystalline substance under a pressure of 1 bar.

Since an enthalpy measurement is made as a difference between an initial and a final state, the reference temperature for enthalpy must be arbitrarily chosen. It is taken to be 298.15 K in all tables. Refer to the discussion of types of thermochemical tables for further details (Secs. 4.2 and 6).

3.2. Symbols

States of aggregation

The symbols and their corresponding descriptions for the states of aggregation are exactly those given by IUPAC.[9,10] They are rewritten here for the convenience of the reader.

Single letters are used to denote the three basic states of aggregation, gas, liquid, and solid, while combinations of letters are used for more subtle descriptions of states.

g	gas or a vapor
l	liquid
s	solid
cd	condensed phase (i.e., either the solid or the liquid state)
fl	fluid (i.e., either the gaseous or the liquid state)
cr	crystalline solid; where polymorphism occurs, it may be necessary to augment the symbol cr with a descriptor for the crystal modification under discussion; the preferred descriptors are Roman numerals, with textual definition of the crystallographic significance of the numerals used
am	amorphous solid
vit	vitreous substance (a glass)
mon	monomeric form
pol	polymeric form (in many cases the monomeric or polymeric character of the entity will be clear from the context without the symbol and the symbol should be used only in cases where ambiguity might result)
sln	solution; in many contexts it will be clear whether a liquid solution or a solid solution is meant, but where this is unclear it must be made clear by supplemental notation
aq	solution in which water is the solvent (an aqueous solution); in the past this symbol has sometimes been used to denote an infinitely dilute aqueous solution, but infinite dilution should henceforward be denoted by the extra symbol ∞.
sat	saturated; the state of equilibrium between phases, whether of a pure substance or a system of more than one component.

Processes

The symbols and their corresponding descriptions for processes are exactly those given by IUPAC.[9,10] The remaining six processes are denoted by the symbols recommended by the Bulletin of Chemical Thermodynamics.[11] The use of special symbols to denote a process are as follows:

vap	vaporization (evaporation) of a liquid
sub	sublimation (evaporation) of a solid
fus	melting (fusion) of a solid
trs	transition of one solid phase to another
mix	the mixing of fluids
sol	the process of solution (dissolution)
r	chemical reaction in general

c	combustion reaction; also can denote critical properties
f	a reaction in which a compound is formed from its elements (formation)
at	a process in which a substance is separated into its constituent gaseous atoms (atomization)
dcm	a process in which a substance decomposes (not given by IUPAC)
dso	a process in which a substance dissociates (not given by IUPAC)
dim	a process in which a substance dimerizes (not given by IUPAC)
dil	the dilution of a solution
gt	glass transition (not given by IUPAC)
hyd	hydrolysis (not given by IUPAC)
ion	ionization (not given by IUPAC)

Fundamental Constants

c	speed of light in vacuum
h	Planck constant
N_A	Avogadro constant
e	elementary charge
F	Faraday constant
R	gas constant
T_0	absolute temperature of "ice point"
k	Boltzmann constant
c_2	second radiation constant

Units

cal	calorie
eV	electron volt
g-atom	a mole of atoms
J	joule
K	kelvin
kcal	kilocalorie
kJ	kilojoule
mol	mole
L	liter

Mathematical Quantities

ln logarithm to the base e
lg logarithm to the base 10 (log)

Spectroscopic Quantities

The spectroscopic symbols, use, and description follow the well-established practices of Moore[12] and Herzberg.[13–16] These sources provide more extensive discussion as to the meaning and use of the various spectroscopic quantities.

The measured quantities often are reported in the literature for a specific isotopic molecule. The thermochemical tables in this publication normally use spectroscopic information for a natural isotopic abundance "molecule." Care should be exercised in noting to which molecule the spectroscopic data pertains.

Å	Angstrom
AP	appearance potential
B_0, B_e	rotational constant
D	centrifugal distortion constant
D_0°	dissociation energy is defined as the enthalpy of the ground-state products relative to the lowest existing level of the molecule; $D_0^\circ = \Delta_{at}H^\circ$ (0 K).
E_i	ionization energy (IP)
E_{ea}	electron affinity (EA)
g_i	quantum (or statistical) weight of the ith electronic state; quantity is the product of the spin multiplicity and state degeneracy of the electronic level under consideration
I_A, I_B, I_C	principal moments of inertia of a molecule
k	Hooke's law force constant
n	number of potential maxima in an internal rotation; also refers to principal quantum number in describing energy levels of atoms
N	number of atoms in molecule
r_e	internuclear distance (for the "equilibrium" structure of the molecule)
V_0	potential barrier to internal rotation
α_e	first-order rotation-vibration interaction constant
ϵ_i	ith electronic energy level
σ	symmetry number
μ	reduced mass of the molecule
ν	observed vibrational fundamental
ω_e	vibrational fundamental for infinitesimal amplitude
$\omega_e x_e$, $\omega_e y_e$	vibrational anharmonicity constants

Thermodynamic and Other Quantities

A_r	relative atomic mass (atomic weight)
C_p	molar heat capacity at constant pressure
C_s	molar heat capacity at saturation
ΔU	change in internal energy
ΔG	change in Gibbs energy, $G = H - TS = U + PV - TS$
ΔH	change in enthalpy, $H = U + PV$
K	equilibrium constant
M_r	relative molecular mass (molecular weight)
p	pressure
T	temperature, in kelvin
t	temperature, in degrees Celsius (°C)
V	volume
Δ	indicates the increment in a given property for a given process or reaction, taken as the value for the final state (or sum for the products) less that for the initial state (or sum for reactants).
$\Delta_f H^\circ$	represents the standard enthalpy of formation, which is the increment in enthalpy associated with the reaction of forming the given compound from its elements in their reference states, with each substance in its thermodynamic standard state at the given temperature.

Experimental Method Techniques

dsc	differential scanning calorimetry
dta	differential thermal analysis
emf	electromotive force
esr	electron spin resonance
glc	gas-liquid chromatography
gpc	gel permeation chromatography
ir	infrared spectroscopy
nmr	nuclear magnetic resonance
tga	thermogravimetric analysis
LLE	liquid-liquid equilibria
VLE	vapor-liquid equilibria
VP/xxxx	vapor pressure/experimental technique
/ebul	= ebulliometric
/Knud	= Knudsen effusion
/stat	= static
/Kems	= Knudsen effusion-mass spectrometry
/Kete	= Knudsen effusion-torsion effusion
/tran	= transpiration
/Lang	= Langmuir free evaporation
/Lams	= Langmuir-mass spectrometry

3.3. Relative Atomic Masses and Natural Isotopic Composition of the Elements

The Table of Atomic Weights of the Elements 1981[7a] is reprinted below. Added to this list are the relative atomic masses for the electron (e-) and deuterium (D). The relative atomic mass for the electron is given by Cohen and Taylor.[8a]

The 1981 report on atomic weights[17] includes a complete review of the natural isotopic composition of the elements and also tabulates the relative atomic masses for selected radioisotopes. This information is required for the conversion of spectroscopic data from that corresponding to specific isotopes to the naturally occurring isotopic abundance. For tabulations issued with dates later than 1985, more recent values are used.

As in the IUPAC report, values in parentheses are used for radioactive elements whose relative masses cannot be quoted exactly without knowledge of the origin of the elements; the value given is the atomic mass number of the isotope of that element of longest known half life. Alternatively, the relative atomic mass of the isotope with the longest known half life or that of a commonly used isotope could be listed, since the relative atomic masses of the individual isotopes are accurately known.

As mentioned in the Introduction (Sec. 1), for tables issued since the Third Edition, values of the molecular masses are based on the 1993 IUPAC recommendations.

Table of relative atomic masses of the elements, 1981
[Pure Appl. Chem. **55**, 1101 (1983), alphabetical order, based on the relative atomic mass, $A_r(^{12}C) = 12$]

Name	Symbol	atomic number	Relative atomic mass
Actinium	Ac	89	227.0278
Aluminum	Al	13	26.98154

3.4 Fundamental Constants and Conversion Factors

The numerical values of the fundamental constants used in our calculations are those obtained by Cohen and Taylor[8a] based on a least-squares adjustment of data existing in 1973. These values have been adopted by CODATA.[8a]

As mentioned in the Introduction (Sec.1), for tables issued since the Third Edition, values of the fundamental constants are based on the 1986 CODATA recommendations.[8b]

Fundamental constants

Quantity	Symbol	Value[a]
Speed of light in vacuum	c	299 792 458(1.2) m s^{-1}
Planck constant	h	6.626 176(36) × 10^{-34} J s
	$h/2\pi$	1.054 588 7(57) × 10^{-34} J s
Avogadro constant	N_A	6.022 045(31) × 10^{23} mol^{-1}
Elementary charge	e	1.602 189 2(46) × 10^{-19} C
Faraday constant, N_Ae	F	9.648 456(27) × 10^4 C mol^{-1}
Absolute temperature of "ice point," O °C	T_O	273.150 0 K
Molar gas constant	R	8.314 41(26) J mol-1 K^{-1}
Boltzmann constant, RN_A^{-1}	k	1.380 662(44) × 10^{-23} J K^{-1}
Second radiation constant, hck^{-1}	c_2	1.438 786(45) × 10^{-2} m K

[a]Numbers in parentheses are the one standard deviation uncertainties in the last digits of the quoted value.

Conversion factors for energy-related units. 1973 CODATA constants

	kJ mol^{-1}	kcal mol^{-1}	eV (per molecule)	cm^{-1}	MHz
1 kJ mol^{-1}	1	0.239 005 7	0.010 364 35	83.593 47	2.506 069 × 10^6
1 kcal mol^{-1}	4.184	1	0.043 364 45	349.755 1	1.048 539 × 10^7
1 eV (per molecule)	96.4846	23.06036	1	8065.479	2.417 970 × 10^8
1 MHz	3.990 313 × 10^{-1}	9.537 077 × 10^{-8}	4.135 701 × 10^{-9}	3.335 641 × 10^{-5}	1
1 cm^{-1}	0.011 962 66	2.859 144 × 10^{-3}	1.239 852 × 10^{-4}	1	2.997 924 × 10^4
1 K (degree)	8.314 41 × 10^{-3}	1.987 19 × 10^{-3}	8.617 349 × 10^{-5}	0.695 030 4[a]	2.083 649 × 10^4
1 hartree	2625.500	627.509 5	27.211 606	2.194 746 × 10^5	6.579 684 × 10^9
1 rydberg	1312.750	313.754 7	13.605 803	1.097 373 × 10^5	3.289 842 × 10^9

[a]This value is inverse of the second radiation constant c_2; $(hc/k)^{-1} = c_2^{-1} = 0.695\ 030\ 4$.

3.5. Temperature Scale

Since the NIST-JANAF Thermochemical Tables deal with properties that vary with temperature, the temperature scale is of significance. The International Temperature Scales are devised to approximate, as closely as possible, the absolute thermodynamic (kelvin) temperature suggested by W. Thomson (Lord Kelvin) in 1854. The International Temperature Scale is established by the Comité International des Poids et Mesures (International Committee of Weights and Measures).

There have been four international temperature scales: The International Temperature Scale of 1927,[18] The International Temperature Scale of 1948 which was renamed the International Practical Temperature Scale of 1948 (IPTS-48) in 1960,[19-20] The International Practical Temperature Scale of 1968 (IPTS-68)[21] and The International Temperature Scale of 1990 (ITS-90).[22]

Our concern in the preparation of the NIST-JANAF Thermochemical Tables is to adjust any experimental measurements to the thermodynamic scale. In practice, this means converting to the ITS-90 scale since it is the currently accepted closest approximation to the thermodynamic scale.

To facilitate temperature adjustments, the article by Corruceini[19] was used for the 1927 to 1948 conversions and the article by Douglas[23] for the 1948 to 1968 conversion. Guildner and Edsinger[24] included a plot showing the deviation of IPTS-69 from the thermodynamic temperatures from 273.16 to 730 K. For conversions to the current scale (ITS-90), there are numerous articles which discuss the conversion of experimental data or smoothed results to the new temperature scale.

Ideal-gas tables of thermodynamic properties derived from statistical mechanics are based on the thermodynamic temperatures (as well as on the values of the physical constants used) and are hence independent of any practical temperature scale. The enthalpy of formation, Gibbs energy of formation, and logarithm of the equilibrium constant might depend on temperature-adjusted data.

For condensed phase tables, the temperature scale conversion is often not necessary and is not made since the correction would be small compared with the uncertainty in the data.

4. Reference States and Conversions

There are three types of tables included in this publication: single-phase, multiphase, and reference state tables. The tables are clearly labeled as to the type at the top of each page and by the state designations associated with the chemical formula. The reference state can involve a single phase or multiphases. The major difference between a multiphase table and a single-phase table is the existence of a discontinuity in each function (or in its first derivative) at a first-order transition temperature.

4.1. Reference State

A related set of thermodynamic property tables requires that there be a reference table of the thermodynamic properties for each element to which all other forms of that element or any compound involving that element may be referred. If the temperature range of interest (0 K to 6000 K herein) can be represented by a single phase for that material (say hydrogen) the tabulated values in the reference table will be smooth and regular. If the temperature range of interest includes more than one phase (say magnesium), there will be a solid phase (from 0 K to 923 K, the melting temperature), a liquid phase (923 K to 1378 K, where the vapor pressure reaches 1 bar), and a gas phase (1378 K to 6000 K), and the tabulated values in the reference table will be discontinuous at these temperatures or phase boundaries. Practical usage dictates that in so far as possible the phase most stable at 1 bar pressure be selected. This practice is followed in these tables, and does lead to discontinuities in the thermodynamic functions. Attention is called to these discontinuities in the reference state tables by insertion of a comment as to the type of transition at the temperature of the phase transition.

Since these tables deal with ideal gases, the pressure is really the fugacity. Calculating a boiling temperature as the temperature at which $\Delta_{vap}G^\circ = 0$ for the process Mg(l)→Mg(g) corresponds to an (ideal) fugacity of 1 bar. This will differ from the real (observed) boiling point at 1 bar which is also different from the real (observed) boiling point at 1 atm. Each of these "three boiling points" corresponds to a different $\Delta_{vap}G^\circ$ value.

With the use of f and °, as in $\Delta_f H^\circ$, the implication is that both the compound in question and its constituent elements are in standard states and that the elements, moreover, are in their reference states; for any given temperature the reference states of the elements will normally be those that are stable at the chosen standard-state pressure and at that temperature. A resulting feature of tabulations of $\Delta_f H^\circ$ and $\Delta_f G^\circ$ as functions of temperature for compounds is that discontinuous changes are sometimes to be seen; these correspond to changes in the stable reference states of the elements, as phase-transition temperatures are passed. Thus, values of $\Delta_f H^\circ$ (SO_2Cl_2,g) would show discontinuous changes at three temperatures corresponding to the transitions S(cr,I)→S(cr,II), S(cr,II)→S(l), and S(l)→1/2 S_2(g), where I refers to rhombic and II to monoclinic crystal forms.

4.2. Single-Phase and Multiphase Tables

A multiphase table contains the data for two or more phases of a pure substance. Each phase is limited to the temperature range in which it is more stable (i.e., has a lower $\Delta_f G^\circ$ than the other phases in the table). There are discontinuities in the properties C_p°, S°, and H° at the temperatures where each phase transforms ($\Delta G^\circ = 0$) to the next phase. Alternatively, the properties of a pure substance can be given in a series of tables where each table is devoted to a single phase. Single-phase tables do not have discontinuities in the properties C_p°, S°, and H° at transition temperatures. Moreover, the properties are extrapolated beyond the transition temperatures into regions where that phase is less stable than its other phases. These characteristics of continuity and extrapolation of properties lead directly to the advantages and problems of single-phase tables. The enthalpy of formation and Gibbs energy of formation may have discontinuities, even in single-phase tables, corresponding to transitions in the reference states.

Single-phase tables are more convenient than multiphase tables in certain computer applications. Interpolation and approximation (curve fitting) apply directly to the continuous properties in a single-phase table. Multiphase tables must first be divided into segments using the stored values of the transition temperatures; then interpolation and approximation must be limited to the temperatures in the pertinent segment.

Single-phase tables are essential in uses that involve unstable phases. This includes phases that persist in a metastable region or those that are unstable at all temperatures. [Such cases abound in the real world.] Single-phase tables are often applied to solid-solid or solid-liquid equilibrium in mixtures, where an unstable phase is "stabilized" in the presence of other components. Analysis of such equilibria often requires liquid or solid properties that are many hundreds of degrees into the metastable region of each pure phase. Single-phase tables are designed to supply these properties, but their preparation is not trivial.

The NIST-JANAF Thermochemical Tables often include estimated glass transitions in the liquid tables. The glass temperature is usually assumed to be ~0.7 times the melting temperature. The heat capacity of the glass is usually assumed to be equal to that of the stable crystalline phase, since existing glass data show a decrease in C_p° to values near those of the crystal. Such tables are, in fact, not single-phase tables but two-phase glass-liquid tables.

The glass transition is of practical concern when thermochemical tables are used near the glass transition temperature of any of the pure liquids. Although the ratio of the glass temperature to the melting temperature can vary from perhaps 0.35 to >0.8, it often is ~0.7. Temperatures this low are not uncommon when tables for liquids are used in the analysis of binary or multicomponent phase diagrams.

It is important to ask whether glass transitions should be included in liquid tables intended for such use. Estimated glass transitions are included for two reasons: the transition is usually observed in supercooled liquids and its inclusion avoids an entropy paradox. The first reason presumes that

glass transitions do occur but cannot be observed in liquids that readily crystallize. The more compelling reason is the avoidance of the paradox in which the entropy of the supercooled liquid (a disordered state) becomes less than that of the stable crystalline state.

The choice remains as to what temperature and what phase should be used as the reference point for enthalpy in the extrapolated single-phase tables. Since 298.15 K was adopted as the reference temperature for multiphase and reference state tables, there is strong incentive for retention of that temperature in single-phase tables. The choice has been made to have the reference at the same arbitrary point in each phase. Thus, the JANAF Thermochemical Tables use a reference temperature of 298.15 K in the table for the high-temperature phase even when that phase is not stable at 298.15 K.

Enthalpies at all temperatures depend on the arbitrary extrapolations needed to relate the observed data to the reference temperature. Each single-phase table has a different reference $\Delta_f H°$ dependent on an arbitrary extrapolation of enthalpy.

For the reference temperature of 298.15 K, the enthalpy at $T \rightarrow 0$ is always negative. This means that the function $-(G° - H)/T$ approaches positive ∞ at $T \rightarrow 0$ and is therefore difficult to interpolate near $T \rightarrow 0$.

4.3. Conversion to SI Units and the Standard-State Pressure

In all previous JANAF Thermochemical Tables, the standard-state pressure was one atmosphere (101 325 Pa) and the unit of energy was the thermochemical calorie (4.184 J). For this publication, the standard-state pressure is changed to one bar (100 000 Pa) and the energy unit to the joule. The values from previous JANAF tabulations have been converted as described below. This information is provided not only to make clear the correspondence between this publication and previous JANAF Thermochemical Tables but also to assist the reader in making comparisons with other tables. This information is the same as that provided in "The NBS Tables of Chemical Thermodynamic Properties."[6]

Conversion of Values in Calories to Joules

For the energy units the defined conversion factor of 4.184 $J \cdot cal^{-1}$ is used.

Conversion for Change in Pressure

The following expressions define the effect of pressure on the properties of all substances.

$$(\partial H/\partial p)_T = V - T(\partial V/\partial T)_p = V(1 - \alpha T),$$
$$(\partial C_p/\partial p)_T = -T(\partial^2 V/\partial T^2),$$
$$(\partial S/\partial p)_T = -V\alpha = -(\partial V/\partial T)_p,$$
$$(\partial G/\partial p)_T = V,$$
$$\alpha \equiv (1/V)(\partial V/\partial T)_p$$

For the small pressure change from 1 atm to 1 bar, the pressure coefficients may be taken as constants for condensed phases. There are no condensed phase cases in this publication for which the pressure coefficients are large enough to affect the tabulated values. Typical values of α for solids are 10^{-5} to 2×10^{-4} K^{-1} and $V < 10^{-3}$ m^3 mol^{-1}. For ideal gases, $V = RT/p$ and $\alpha = R/pV = 1/T$. The pressure coefficients for gases are large enough to affect high-accuracy data. In practice the only properties tabulated here that are affected are $S°(T)$ and $-(G°(T) - H°[298.15\ K])/T$ for all gases, and $\Delta_f G°(T)$ and lg K_f for any substance whenever gases are involved.

The conversion equations used for the change in standard-state pressure are listed below together with some that apply to thermal functions. Superscripts ° and * denote values at 1 bar and 1 atm, respectively. These equations apply to the small change in pressure from 1 atm to 1 bar.

For all substances, exactly for ideal gases and within the limit of experimental inaccuracy for all other phases:

$$\Delta_f H°(T) - \Delta_f H*(T) = 0,$$
$$[H°(T) - H°(T_1)] = [H*(T) - H*(T_1)] = 0,$$
$$C_p°(T) - C_p*(T) = 0,$$

where T_1 is a reference temperature.

For condensed phases, within the limit of experimental inaccuracy:

$$S°(T) - S*(T) = 0$$
$$G°(T) - G*(T) = 0$$

For substances that are gaseous:

$$S°(T) - S*(T) = R \ln p*/p°$$
$$= R \ln \frac{101325}{100\,000} = 0.109\ 444\ J \cdot K^{-1}\ mol^{-1}.$$

For substances that are gaseous at T but may or may not be gaseous at T_1:

$$-[G°(T) - H°(T_1)]/T + [G*(T) - H*(T_1)]/T = R \ln p*/p° \text{ as for } S.$$

$$[G°(T) - G°(T_1)] - [G*(T) - G*(T_1)] = R(T - T_j)\ln p*/p°,$$

where $T > T_j \geq T_1$ and T_j is the temperature at which the function begins to apply to the ideal gas, usually the boiling temperature at 1 bar.

For each substance with gases in its formation reaction:

$$\Delta_f G°(T) - \Delta_f G*(T) = -\delta RT \ln 1.013\ 25 = -0.032\ 63\ \delta\ kJ\ mol^{-1} \text{ at } 298.15\ K.$$

where δ is the net increase in the number of moles of gas in the formation reaction.

Conversions for Entropies of Gases

To convert from:	$S°$(g,0.1 MPa) / J·K^{-1} mol^{-1}	$S*$(g,1 atm) / cal·K^{-1} mol^{-1}	$S^{\dagger}$ (g,1 atm) / J·K^{-1} mol^{-1}
To:	Use		
$S°$(g,0.1 MPa) / J·K^{-1} mol^{-1}	$= S°$	$4.184(S* + 0.026\ 157)$	$S^{\dagger} + 0.109\ 442$
$S^{\dagger}$ (g,1 atm) / J·K^{-1} mol^{-1}	$= S° - 0.109\ 442$	$4.184\ S*$	$S^{\dagger}$
S(g,0.1 MPa) / cal·K^{-1} mol^{-1}	$= S°/4.184$	$S* + 0.026\ 157$	$(S^{\dagger} + 0.109\ 442)/4.184$
$S*$(g,1 atm) / cal·K^{-1} mol^{-1}	$= (S° - 0.109\ 442)/4.184$	$S*$	$S^{\dagger}/4.184$

$S°$ entropy for a gas at 0.1 MPa in J·K^{-1} mol^{-1}.
$S*$ entropy for a gas at 1 atm in cal·K^{-1} mol^{-1}.
$S^{\dagger}$ entropy for a gas at 1 atm in J·K^{-1} mol^{-1}.

4.4. Boiling Temperature and the Standard-State Pressure

In these tables, the defined pressure for the standard state is 1 bar (100 000 Pa). As stated by IUPAC,[9] the present recommended change in the standard-state pressure carries no implication for "standard pressures" used in other contexts, e.g., the convention that "normal boiling points" refer to a pressure of 1 atm (101 325 Pa). Instances may occur where it is desirable to adopt yet other values for $p°$ and so all authors must clearly state the value adopted.

In these tables, the temperature at which $\Delta_r G° = 0$ for the process liquid to gas, refers to a fugacity of 1 bar. Typically the real (i.e., observed) boiling point (corresponding to a nonideal gas) is slightly higher. In many cases the experimental uncertainties in measuring a boiling point (at 1 bar) and the uncertainties in the calculated value due to uncertainties in the thermal functions make this difference meaningless. Such a situation exists whether the standard-state pressure is 1 bar or 1 atm.

The phrase "boiling point" must be used carefully for other reasons. Care must be exercised such that the boiling process is indeed defined. Two examples which illustrate this point are MgO and LiF. Magnesium oxide does not vaporize congruently (so that the total vapor pressure depends on the ambient oxygen potential), whereas LiF vaporizes congruently but monomer, dimer, and trimer species exist in the vapor.

5. Evaluation of Thermodynamic Data

Interconsistency

The basic aim of these thermodynamic property tables is to provide a related and consistent set of enthalpies of formation and Gibbs energies of formation. This allows the prediction of the enthalpy and Gibbs energy changes and the equilibrium constants for any reaction among the constituents of the tables.

The enthalpy of formation and Gibbs energy of formation are related to each other through the entropy of formation of the substance. Self-consistency can be assured by use of this constraint to derive any one property from selected values of the other two. The entropy, which is an absolute quantity in thermochemical calculations, is suitable for one of the selected properties. The enthalpy of formation is convenient for the other, since enthalpy of reaction is the most commonly measured link between different substances.

Enthalpy changes are relative quantities, so it is important to relate each substance to a consistent base. This is done by referring each enthalpy of formation to the chemical elements in their standard reference states. By convention, the enthalpy of formation of an element in its standard reference state is zero at all temperatures.

The reference state table may involve a single phase or several phases and examples of both kinds are found in this compilation. For elements which are solid at room temperature, the reference state is normally the stable solid state(s) up to the melting point, the liquid up to the boiling point at 1 bar, and thereafter the gas phase which may be monatomic or diatomic. For other elements, the choices for the reference states are:

(1) the ideal monatomic gas for the inert rare gases and the electron gas He, Ne, Ar, Kr, Xe, Rn, and e^-. The classical statistical mechanical values are assumed for $H°(T) - H°(0)$ for the electron.

(2) the ideal diatomic gas for the following gases: H_2, D_2, N_2, O_2, F_2, and Cl_2.

(3) crystalline white phosphorus and the ideal diatomic gas, $\frac{1}{2}P_2(g)$. The early JANAF publications used red phosphorus as the reference state. Although red phosphorus is the more stable form, it is less well characterized and its properties are less reproducible.

(4) the ideal diatomic gas combined with the appropriate condensed phases for Br_2, I_2, and S; for sulfur, the gaseous portion of the reference state is $\frac{1}{2}S_2(g)$.

(5) graphite (Acheson-spectroscopic grade) for carbon at all temperatures.

These choices are arbitrary and vary in different compilations. Enthalpies or Gibbs energies of formation taken from different sources should be converted to common reference states before use.

The establishment of reference states is the first step in any scheme for interconsistency. The next step, ideally, would be to solve simultaneously for all $\Delta_f H°$, $\Delta_f G°$, $S°$ using all the suitable data for $\Delta_r H°$, $\Delta_r G°$, $\Delta_r S°$, and $S°$. This would provide values for enthalpies, Gibbs energies, and entropies which, when combined, would yield the minimum overall deviations from the measured values. Simultaneous solution is limited in practice to small groups of interrelated substances.

We have used this simultaneous approach in a limited way for treating groups of interrelated fluorides. Dr. John L. Haas, Jr. (U.S. Geological Survey) has treated, simultaneously, the data for some geologically important systems as a function of temperature and pressure.[25] Dr. J. Brian Pedley (University of Sussex) has treated $\Delta_r H°$ data for several systems, the most pertinent involving all the diatomic oxides.[26] Dr. Vivian Parker and Dr. David Garvin (NBS) have refined the latter method and applied it to some species that were adopted by CODATA.[27] JANAF policy is to use the results of these treatments.

Since simultaneous solution has not been attempted for all substances it is necessary to fix, simultaneously when possible, certain key values for common substances. These are then used in the usual sequential way to help fix other substances. JANAF policy is to adopt the key values recommended by the CODATA Task Group for Key Values in Chemical Thermodynamics.[28] Exceptions to this policy only occur when additional recent data are available.

Because of the many revisions of these tables, perfect interconsistency is not always attained. However, any inconsistency of the tables is a prime concern and is a cause for revision if the effects are of the same order of magnitude as the stated uncertainties.

An approximate type of consistency relates to trends in properties within families in the periodic table. Expected trends can aid both in estimation of missing data and in evaluation of observed data, for example, in a series from fluoride to iodide or from polyhalide to monohalide.

5.1. General Evaluation Techniques

Heat Capacities and Enthalpy Difference

The evaluation of reported values is a judgmental process, but the analysis should be as objective as possible and therefore certain ground rules must be established. The first step involves the examination of a plot of all information so that a general idea of the agreement can be visually obtained. If certain data sets differ from the majority, they are examined for possible causes of the difference. Calibration data, sample purity, and experimental scatter are checked. If the source of error can be located, the data are given appropriately less weight. Otherwise all data of equal reliability are considered equal, even if they disagree. Such data are then smoothed by a weighted least-squares curve fit. Enthalpy data are smoothed similarly and heat capacities are derived exactly from the differentiated polynomial. The smoothing of enthalpy data often requires constraining the fit so that it passes through zero at the reference temperature. Additional constraints are often used to fix the heat capacity at 298.15 K or to join enthalpy data smoothly with low-temperature heat capacities.

Transitions

The evaluation of solid-state transitions involves first the recognition of the type of transition, which may not always be obvious. A first-order transition such as fusion involves a discontinuous change of enthalpy and entropy at the transition point, whereas second-order transitions involve only discontinuities in heat capacity. Because of impurities and other factors, first-order transitions often do not occur sharply at one temperature; instead, they spread a little on either side and are sometimes difficult to distinguish from λ-type second-order transitions.

Many enthalpies of fusion and enthalpies of solid-state transitions are obtained from enthalpy measurements. Here the enthalpies are given directly by the difference in enthalpy at the transition temperature. Normally, the enthalpy above and below can be smoothly extended to the temperature of transition, although the transition temperature may not be clearly obtainable from the enthalpy data.

The enthalpies of the transitions involving vaporization and sublimation are evaluated from equilibrium data by the second- and third-law methods. When reliable calorimetric measurements are available, the adopted enthalpy of transition is usually based on them.

Equilibrium

Perhaps the most significant facts to be established in evaluating equilibrium data are whether equilibrium was attained and whether the process was properly described. For example, in a sublimation process the most accurate measurements are valueless if the vapor phase is not uniquely defined. If polymerization or breakdown might have occurred, it is important to establish the exact reaction first. Because mass spectroscopy has shown that vapor phases are often extremely complex, it is almost a requirement that the vapor composition be established by a mass spectrometer before equilibrium data can be accepted. Some methods of measurement are less accurate than others and should be given less weight. For example, equilibria determined in a mass spectrometer may have significant uncertainty because of the approximations involved in obtaining absolute pressures. On the other hand, measurements of the electromotive force of reversible cells can have great accuracy. Mass spectra provide identification

of the vapor species while a very precise emf measurement tells nothing as to the reaction which is occurring. Each method has inherent limitations; these may be more critical in some uses than in other uses. Clues to the existence of these limitations often appear in the second- and third-law analyses.

The Second-Law Method

Starting from the equation $\Delta G^\circ = -RT \ln K$, by differentiation with respect to T and substitution of $d(\Delta G^\circ)/dT = -\Delta S^\circ$, we obtain $\Delta H^\circ = RT^2 d(\ln K)/dT$, the well-known van't Hoff equation. By substituting $dT = -T^2 d(1/T)$, one obtains $\Delta H^\circ = -R\, d(\ln K)/d(1/T)$; thus, the slope of ln K versus $1/T$ plot is $-\Delta H^\circ/R$. If ΔH° is constant, then the slope is constant and the plot is a straight line. Since the variation of ΔH° with temperature is often quite small, it is customary to assume a straight-line relationship. This method of obtaining enthalpies of reaction from equilibrium measurements is known as a "second-law" calculation. For greatest accuracy the equilibrium measurements should extend over a wide range of temperature, and in this case ΔH° is usually not constant.

Curvature corrections can be applied by assuming a specific form for the variation of ΔH° with temperature. In this manner we can calculate $\Delta_r H^\circ$ (298.15 K) from $\Delta_r H^\circ$ (T). The effects of such corrections may be of significance. It should be noted that the second law cannot be applied to a single observation, but the third-law method, which is described below, can be so used. The second-law method also can be applied when only relative values of the equilibrium constant are available, for example, from mass-spectroscopic intensity measurements.

The Third-Law Method

The "third-law" method is based on a knowledge of the absolute entropy of the reactants and products. It allows the calculation of a reaction enthalpy from each data point when the change in the Gibbs energy function for the reaction is known. The Gibbs energy function used here is defined as

$$\text{gef}(T) = [G^\circ(T) - H^\circ(298.15\ \text{K})]/T$$

and is easily calculated from the relation

$$\begin{aligned} S^\circ/(T) &= -[G^\circ(T) - H^\circ(T)]/T \\ &= [H^\circ(T) - H^\circ(298.15\ \text{K})]/T \\ &\quad - [G^\circ(T) - H^\circ(298.15\ \text{K})]/T \end{aligned}$$

thus,

$$\text{gef}(T) = -S^\circ(T) + [H^\circ(T) - H^\circ(298.15\ \text{K})]/T$$

From the definition we can write for the change in a reaction

$$\Delta G^\circ/T = \text{gef}(T) + \Delta H^\circ(298.15\ \text{K})/T = -R \ln K,$$

thus,

$$\Delta H^\circ(298.15\ \text{K})/T = -R \ln K - \Delta\text{gef}(T),$$

where Δgef signifies gef(products) − gef(reactants).

In the NIST-JANAF Thermochemical Tables, Gibbs energy functions are based on an enthalpy reference temperature of 298.15 K and thus yield enthalpy changes at 298.15 K regardless of the temperature of the reaction. It should be noted that the Gibbs energy function in a single-phase table is based on the enthalpy of that phase at 298.15 K even though the phase may not be stable at 298.15 K. This differs from the usual convention of combining all condensed phases into one multiphase table such that the enthalpy of reaction refers to the phase stable at the reference temperature. In the JANAF tables the functions always refer to the designated phase for 298.15 K regardless of its stability. For example, if the vapor pressure over liquid copper is analyzed using Cu(l) Gibbs energy functions, the result is the enthalpy of vaporization of the liquid at 298.15 K. To calculate the enthalpy of sublimation of Cu(cr) it is necessary to add the enthalpy of fusion at 298.15 K, which is the difference in the enthalpy of formation of Cu(l) and Cu(cr) at 298.15 K. It should also be noted that Gibbs energy functions are always negative, thus the negative of the function is usually tabulated and the proper sign must be remembered when using these functions.

The analysis of data by the third-law method is generally considered superior to the second-law analysis. It is definitely superior if the Gibbs energy functions are accurately known because each equilibrium point yields one value for the enthalpy change. These values will often reveal trends that indicate nonequilibrium or erroneous values in the equilibrium constants of a set of data. If the data are good, the second-law value should agree. When the Gibbs energy functions are estimated, the third-law values derived from them must be handled carefully. Values that are constant and that agree with the second-law enthalpy indicate that the Gibbs energy functions and equilibrium data are mutually consistent. A drift with temperature of the third-law values indicates errors in either the data or the functions. The magnitude of such drifts is often given in the table write-up and represents the entropy change required to bring the second- and third-law values into agreement. If the drift is within the uncertainty of the experimental entropy, then the data are acceptable. Drifts that are much larger than reasonable entropy errors generally indicate failure to attain equilibrium or improperly estimated Gibbs energy functions.

We have found a combination of the two methods to be so valuable that a third-law calculation is always accompanied by a second-law treatment of the same data. The calculation is done in ascending temperature order to give $\Delta_r H^\circ$(298.15 K) and its deviation from the mean along with the calculated log K and its deviation from the least-square line. Third-law analysis enables bad points to be seen as deviations from the general trend of the differences; thus the method can be used even when the Gibbs energy functions are estimated. If these bad points are located on the ends of the data set, the second-law line often fits them quite well and by itself does not arouse suspicion. But the dropping of such points can bring widely discordant ΔH° values into agreement with each other and often with the third-law values.

In our analysis of equilibrium data, tabulations for both the second- and third-law results are normally given. In addition, we often list values for the drift of δS, as defined by

$$- \text{drift} = \delta S = \Delta_r S^\circ \text{ (2nd law, 298.15 K)} - \Delta_r S^\circ \text{ (3rd law, 298.15 K)}$$

δS previously called a drift (in $\Delta_r H^\circ$), gives a direct comparison of the deviation of the calculated second-law entropies from our adopted functions. The current policy is to use δS rather than drift. $\Delta_r S^\circ$ (2nd law, 298.15 K) is not calculated, however, via the usual second-law method or the method.[29,31] It is instead derived from the slope of the assumed linear temperature dependence of the deviations from the mean of the third-law enthalpies of reaction. Our experience indicates that this method agrees closely, but not exactly, with the method.

6. Construction of the Tables

The NIST-JANAF Thermochemical Tables consist of thermal functions and formation functions, both of which are temperature dependent. The thermal functions consist of heat capacity, enthalpy increments, entropy, and Gibbs energy function. The normal relationships hold between thermal functions:

$$H^\circ(T) = \int_0^T C_p^\circ(T)\mathrm{d}T,$$

$$S^\circ(T) = \int_0^T [C_p^\circ(T)/T]\mathrm{d}T,$$

$$[G^\circ(T) - H^\circ(298.15\text{ K})]/T = -S^\circ(T) + [H^\circ(T) - H^\circ(298.15\text{ K})]/T.$$

The formation functions consist of enthalpy of formation, Gibbs energy of formation, and the logarithm of the equilibrium constant of formation. Enthalpies of formation at temperatures other than 298.15 K require a knowledge of enthalpies of the reference elements:

$$\Delta_f H^\circ(T) = \Delta_f H^\circ(298.15\text{ K}) + [H^\circ(T) - H^\circ(298.15\text{ K})]_{\text{compound}} - \Sigma[H^\circ(T) - H^\circ(298.15\text{ K})]_{\text{elements}}.$$

The Gibbs energy of formation is readily calculated from the enthalpy of formation when the entropies of the elements are known. Thus

$$\Delta_f G^\circ(T) = \Delta_f H^\circ(T) - T\{S^\circ(T)_{\text{compound}} - \Sigma S^\circ(T)_{\text{elements}}\}.$$

The logarithm of the equilibrium constant of formation is then found from the relation $\Delta_f G^\circ(T) = -RT \ln K_f$.

Solid Phase Thermal Functions

The solid phase thermal functions are derived from recommended heat capacity and/or enthalpy increment values. Although the NIST-JANAF Thermochemical Tables place more emphasis on high temperatures ($T > 298.15$ K), it is desirable have data in the temperature range of $T \rightarrow 0$ to 298.15 K. There is no basic difference in evaluating low-temperature data, but many more heat capacity points are needed to describe fully the large curvature in the temperature dependence of the heat capacity. In order to evaluate the enthalpy increment it is necessary to start with the temperature $T = 0$ and integrate up to 298.15 K; then the value at 298.15 K is subtracted from the intermediate values, giving negative values for the enthalpy below 298.15 K.

The tables extend to well above the normal melting point to provide data in a metastable region which in this case is a superheated region. Explanations are inserted in the tabulations to indicate the end of the phase stability and any solid-state transitions.

Liquid Phase Thermal Functions

The construction of the liquid single-phase thermal functions is identical with that used for the solid phase; however, the required data at 298.15 K are not usually readily available. The data are obtained by calculating a preliminary table using the chosen heat capacities with zero values for $\Delta_f H^\circ$ (298.15 K) and S° (298.15 K). The correct starting values are then determined by comparing the values from the tables of crystal and liquid, using the following equations:

$$\Delta_{\text{fus}} H^\circ = \Delta_f H^\circ(T_{\text{fus}},\text{l}) - \Delta_f H^\circ(T_{\text{fus}},\text{cr}),$$

$$\Delta_{\text{fus}} S^\circ = \Delta_{\text{fus}} H^\circ / T_{\text{fus}} = S^\circ(T_{\text{fus}},\text{l}) - S^\circ(T_{\text{fus}},\text{cr}).$$

The correct values at 298.15 K may be obtained from the above relations. A typical liquid table is extrapolated both below the melting point (if the melting point is above 298.15 K) and above the boiling point to facilitate interpolation and to provide data in the metastable regions, both in the supercooled and superheated regions. A glass transition may be included in which case the tabulation becomes a multiphase table.

Gas Phase Thermal Functions

The gas phase thermal functions are generated using statistical mechanical relationships. Minimal data required for the various types of molecules are summarized below. Some of the equations used are given in Sec. 6.1 on Calculational Methods. The relative molecular mass is required for all molecules. Minimum information required is:

Monatomic species:
- Low-lying atomic energy levels and their statistical weights.

Diatomic species:
- Spectroscopic parameters such as the vibrational-rotational constants, symmetry number, and low-lying electronic energy levels.

Linear polyatomic species:
- Rotational constant, symmetry number, vibrational frequencies, and low-lying electronic levels.

Nonlinear polyatomic species:
- Principal moments of inertia, symmetry number, vibrational frequencies, and low-lying electronic levels.

Multiphase Tables

Tables which show only values for the stable phases at 1 bar pressure are multiphase tables. Multiphase tables can always be recognized by the presence of solid lines, indicating phase transitions, on the table. They are prepared in a manner similar to tables for condensed phases. The functions are evaluated in the same manner as for a solid up to the first transition point; then the enthalpy and entropy of transition are added and the integration is continued using the heat capacities of the next phase. At each transition, the above process is repeated.

6.1. Calculational Methods

The calculation of the temperature-dependent values of the thermal function is performed using a variety of procedures. Some of these procedures were developed internally while others were developed at other locations. A general description of the traditional equations used in the JANAF project follows. Numerous higher order calculational schemes are used whenever the data are sufficient. These procedures are detailed on the appropriate tables.

In gas phase calculations, all thermodynamic variables are calculated in dimensionless form, e.g., C_p/R to at least seven significant figures. This is an arbitrary choice since most data do not warrant this accuracy. This has been done to permit the calculation of the crossover temperatures and enthalpies between single-phase tables accurately and to permit conversion to the desired units without loss of accuracy. The printed tables, however, will only contain three decimal places. Condensed phase tables do not depend directly on R (the gas constant) and they are not calculated in dimensionless form, but are calculated to five decimal places for units conversion.

Condensed Phase Species

Thermodynamic data for condensed states are derived from either measured or estimated information. The thermochemical table is obtained normally by the appropriate integration of heat capacity data. At the. appropriate temperatures, transition enthalpies are added to the enthalpy total, while the quotient of the transition enthalpy divided by the thermodynamic temperature is added to the entropy total.

Gaseous Species

Calculation of the contributions of rotation and translation involves the use of quantum statistics, but to obtain a numerical solution, the quantum statistics are usually replaced by classical statistics at temperatures above about 10 K; below 10 K this classical approximation no longer holds. For this reason the equations presented here fail in the vicinity of $T \rightarrow 0$. In agreement with the third-law concept, C_p° and S° are zero at $T \rightarrow 0$. For a reference element, $\log K_f$ is zero at $T \rightarrow 0$, while for compounds the absolute values of the Gibbs energy function and $\log K_f$, become infinite at $T \rightarrow 0$, for the choice of the enthalpy reference temperature of 298.15 K.

In addition, classical statistics can sometimes lead to erroneous results at high temperatures. For example, the classical approximation could give abnormally high C_p° values for a diatomic molecule having a shallow potential energy curve.

The functions calculated for gases are obtained, in general, from molecular constants that have been adjusted to the natural isotopic abundance. Normally, the approximation of adjusting the molecular parameters by a weighting according to a weighted natural isotopic abundance can be made. The proper correction (which is used for all reference states) is based on a weighted isotopic average of the tabulations.

An electronic term of unit statistical weight lying at 30 000 cm^{-1} and above contributes a negligible amount to the thermodynamic functions at temperatures of 6000 K and below. On the other hand, a number of such terms cannot be neglected. In these cases, the number of terms and their values have been summed and their contribution included.

Some fundamental vibrational frequencies have been estimated by analogy with related molecules. Occasionally, two or more fundamentals are estimated at the same value. This is not to be confused with a true degeneracy which is indicated by placing the degeneracy value in parentheses following the frequency. However, when the information has been taken from another compilation, the degeneracies indicated by the compiler have been retained.

The method used in generating the thermal functions depends not only on the quality/quantity of information available but also on the specifics of the nature of the information (e.g., split ground state, shallow potential wells, etc.). The gas phase tables are generated using the following relationships unless stated otherwise. These relationships are given in Mayer and Mayer[30] and Pitzer and Brewer.[31]

Use of a more sophisticated approach will always be noted and details given on the appropriate tables. The more common alternative approaches are given by McBride and Gordon[32] and McDowell[33] for monatomic and polyatomic gases. For many diatomic gaseous molecules (the alkali metal dimers, the alkaline earth metal dimers, the halogens, hydrogen, deuterium, nitrogen, oxygen, sulfur), a direct summation technique has been used. This technique, stated explicitly on the individual tables, involves a summation over the individual rotation-vibrational energy levels for each electronic state in the partition function expression. In addition, the summation is terminated at the dissociation energy for a particular electronic state of the diatomic molecule; although in some cases, the metastable states (above the dissociation energy) are included in the summation.

6.1.1. Ideal Monatomic Gas

(a) Translation

$$C_p^\circ/R = 5/2,$$

$$[H^\circ(T) - H^\circ(0\,\mathrm{K})]/RT = 5/2$$

$$S^\circ/R = 3/2 \ln M_r + 5/2 \ln T + 5/2 + \ln \frac{k}{p^\circ}\left(\frac{2\pi k}{Nh^2}\right)^{3/2},$$

$$-[G^\circ(T) - H^\circ(0\,\mathrm{K})]/RT = 3/2 \ln M_r + 5/2 \ln T + \ln \frac{k}{p^\circ}\left(\frac{2\pi k}{Nh^2}\right)^{3/2}.$$

(b) Electronic

$$C_p^\circ/R = T^2 \frac{d^2 \ln Q}{dT^2} + 2T \frac{d \ln Q}{dT}$$

$$[H^\circ(T) - H^\circ(0\,K)]/RT = T \frac{d \ln Q}{dT^2},$$

$$S^\circ/R = T \frac{d \ln Q}{dT^2} + \ln Q,$$

$$-[G^\circ(T) - H^\circ(0\,K)]/RT = \ln Q,$$

where

$$Q = \sum_i g_i \exp(-c_2\epsilon_i/T),$$

where ϵ_i is in cm^{-1} and the electronic levels to be included are discussed on the appropriate gas phase table.

6.1.2. Ideal Diatomic Gas

(a) Translation: Same as in I(a).

(b) Rotation

$$C_p^\circ/R = 1 + (c_2B/T)^2/45,$$

$$[H^\circ(T) - H^\circ(0\,K)]/RT = 1 - (c_2B/T)/3 - (c_2B/T)^2/45.$$

$$S^\circ/R = 1 - \ln(c_2B\sigma/T) - (c_2B/T)/90.$$

$$-[G^\circ(T) - H^\circ(0\,K)]/RT = -\ln(c_2B\sigma/T) + (c_2B/T)/3 + (c_2B/T)^2/90,$$

where

$$B = (B_e - \alpha_e/2);$$

in cm^{-1} when spectroscopic constants are available, or

$$B = h/8\pi^2cI = 2.799\,320 \times 10^{-39}/I;$$

in cm^{-1} when calculated from molecular model, I in $g \cdot cm^2$.

(c) vibration

$$C_p^\circ/R = u^2e^{-u}/(1 - e^{-u})^2,$$

$$[H^\circ(T) - H^\circ(0\,K)]/RT = ue^{-u}/(1 - e^{-u}),$$

$$S^\circ/R = ue^{-u}/(1 - e^{-u}) - \ln(1 - e^{-u}),$$

$$-[G^\circ(T) - H^\circ(0\,K)]/RT = -\ln(1 - e^{-u}),$$

where

$$u = c_2(\omega_e - 2\omega_e x_e)/T;$$

when spectroscopic constants (in cm^{-1}) are available, or

$$u = c_2\omega/T;$$

where ω (in cm^{-1}) is the fundamental frequency of a harmonic oscillator.

(d) Corrections for anharmonic vibrations

$$C_p^\circ/R = \frac{16\gamma}{u} - \frac{\delta u^2 e^e}{(e^u - 1)^2} + \frac{u^2e^u(2\delta e^u - 4Xu - 8x)}{(e^u - 1)^3} + \frac{12Xu^3e^{2-u}}{(e^u - 1)^4},$$

$$[H^\circ(T) - H^\circ(0\,K)]/RT = \frac{8\gamma}{u} + \frac{u(\delta e^u - 2X)}{(e^u - 1)^2} + \frac{4Xu^2e^u}{(e^u - 1)},$$

$$S^\circ/R = \frac{16\gamma}{u} + \frac{\delta}{(e^u - 1)} + \frac{\delta u e^u}{(e^u - 1)^2} + \frac{4Xu^2e^u}{(e^u - 1)^3},$$

$$-[G^\circ(T) - H^\circ(0\,K)]/RT = \frac{8\gamma}{u} + \frac{\delta}{(e^u - 1)} + \frac{2Xu}{(e^u - 1)^2},$$

where $u = (\omega_e - 2\omega_e x_e)(c_2/T)$, $X = \omega_e x_e/\omega_e$, $\delta = \alpha_e/B_e$, and $\gamma = B_e/\omega_e$; ω_e, $\omega_e x_e$, B_e and α_e are in cm^{-1}.

(e) Electronic

Same as I(b) when the ith-state vibrational partition function, Q_v^i, and the ith-state rotational partition function, Q_r^i, are equal to the respective ground-state partition functions. In this case the partition function

$$Q = Q_tQ_vQ_r^i \sum_i Q_e^i,$$

otherwise all the thermodynamic functions are derived from

$$Q = Q_t[\sum_i Q_e^iQ_v^iQ_r^i,$$

where Q_t is the translational partition function and

$$Q_e^i = g_i \exp(-c_2\epsilon_i/T).$$

6.1.3. Linear Polyatomic Molecule

(a) Translation: Same as in I(a).

(b) Rotation: Same as in II(b).

(c) Vibration: Same as in II(c) for $3N - 5$ vibrational degrees of freedom.

(d) Corrections for anharmonic vibrations: This contribution is normally neglected.

(e) Electronic: Same as II(e) where levels and quantum weights are known.

6.1.4. Nonlinear Polyatomic Molecule (Rigid Rotator, Harmonic Oscillator)

(a) Translation: Same as in I(a).

(b) Rotation:

$$C_p^\circ/R = 3/2,$$

$$[H^\circ(T) - H^\circ(0\,K)]/RT = 3/2,$$

$$S°/R = \frac{3}{2} + \frac{1}{2}\ln(I_A I_B I_C) - \ln\sigma + \frac{3}{2}\ln T + (-\frac{3}{2}\ln\frac{h2}{8R\pi°} + \frac{1}{2}\ln\pi)$$

$$-[G°(T) - H°(0\,K)]/RT = \frac{1}{2}\ln(I_A I_B I_C) - \ln\sigma + \frac{3}{2}\ln T + (-\frac{3}{2}\ln\frac{h2}{8R\pi°} + \frac{1}{2}\ln\pi)$$

(c) Vibration
Same as II(c) for $3N - 6$ vibrational degree of freedom.

(d) Corrections for anharmonic vibrations.
This contribution is normally neglected.

(e) Electronic
Same as II(e) where levels and quantum weight are known.

6.2. Dates

At the bottom of the tabulation side of each table, there are one or two dates. These dates refer to the approximate time at which the evaluation for these tables was completed. The data for the most recent and the preceding evaluation are given. These dates will be at the bottom of the page at the right-hand side and left-hand side, respectively. Previously, all revision dates had been listed. Current practice will limit the dates to two. For the gas phase tables, the standard-state pressure is given in parentheses after the date(s). If the dates are identical, then the difference in this current table and its predecessor lies in the changes due to the standard-state pressure. Contrary to previous practice, the latest issue date of each table is not given in either of the two indices in this publication.

7. Additions, Revisions, and Corrections

In this Fourth Edition there are numerous typographical errors from the Third Edition which have been corrected. However, there are calculation errors in the formation properties for the following compounds: $AlCl_4Na$(cr), BHO_2(cr), BH_2O_2(g), $B_8K_2O_{13}$(l), Be_4O_4(g), Br_3OP(g), Br_3PS(g), CH^+(g), CN(g), CO(g), CTi(cr), C_2H_2(g), C_2Li_2(cr), C_2Mg(cr), CH_3Cl_3Si(g), CH_3F_3Si(g), ClFMg(g), ClH_4N(cr), Cl_4Mo(g), Cl_4Pb(g), Cl_4Ti(cr, l, cr/l), F_2Hg_2(cr), F_2Ti(g), FeH_2O_2(g), HP(g), HS(g), H_2P(g), H_3P(g), Hg^+(g), LiO^-(g), $Mg_3P_2O_8$(cr), OS_2(g), W(g), W^+(g), Zr(g), and Zr^+(g). These also have been corrected.

In addition new tables have been constructed many halogen oxides. These include 5 iodine oxides, 5 bromine oxides, 7 chlorine oxides, and 4 oxygen fluorides.

8. Acknowledgments

The Fourth Edition of the NIST-JANAF Thermochemical Tables has been prepared with the financial support and cooperation of the Standard Reference Data Program of Technology Services and the Physical and Chemical Properties Division of the Chemical Sciences and Technology Laboratory. Many thanks are extended to Dr. John R. Rumble, Jr. and Dr. Richard F. Kayser for their assistance in formulating the completion of this work. This effort involved the conversion of the electronic files from the Third Edition of this work, a reformatting for the preparation of both electronic and hard copy of this publication. With numerous comments from the scientific community and the conscientious and dedicated work on the part of the SRDP staff, this Fourth Edition is a much improved publication. Numerous typographical errors were detected and corrected. Although many were involved in this transcription process, special thanks are due Sabina A.-M. Crisen, Linda Diane Decker, and Constance L. Seymour. It was their hard-driving efforts that brought this endeavor to a close and added significant value to the publication. Early efforts in this conversion process benefitted from the help of Mary E. Dal-Favero, Judith T. Calabrese, and Cheryl Williams Levey.

This Fourth Edition of the NIST-JANAF Thermochemical Tables has included many changes due to typographical, numerical, and grammatical errors noted by many scientists. Thanks are extended to John Angus, Darrell Butt, Edward B. Dismukes, Denton S. Ebel, David M. Gay, Goran Grimvall, Robert S. Hiers, III, Alan W. Irwin, K. T. Jacob, Pinchus Laufer, Jim Lyons, John Norman, S. S. Pandit, Cesar Sastri, Theordore Selover, William R. Smith, Alan N. Syverud, Yutaka Tanaka, and Michael R. Zachariah.

The effort devoted to the publication of the Third Edition (via an electronic format) made the transition here easier. The editor gratefully acknowledges the financial support of the U.S. Department of Energy (Contract No. DE AC22-81PC41514) for the publication of the Third Edition. The encouragement and continued cooperation by our Technical Project Officer, Mr. F. E. Spencer, Jr., is also greatly appreciated. The preparation of the individual JANAF Thermochemical Tables was supported by the DOE (Mr. F. E. Spencer, Jr.) and the AFOSR (Dr. L. H. Caveny). The authors sincerely appreciate the support of those two organizations. A special note of thanks is extended to Dr. Joseph F. Masi (AFOSR, retired) who fought for the support and continuation of this project during some very difficult funding periods in the late 1960s and early 1970s.

The JANAF Thermochemical Tables have benefitted substantially over the past 35 years from the many scientists scattered throughout the world who have provided us with unpublished data, data in advance of publication, clarifications of fine points of experimentation and interpretation, and free and helpful discussions on a wide range of scientific matters. Our heartfelt thanks are long overdue to all involved.

The preparation of the Third Edition publication required the help and cooperation of many individuals. Extensive assistance with the computer application in all aspects of the project (especially assembling the indices and the tabulation printouts) was received from Dr. Milton D. Marks. The initial conversion of the tables into the new style and format was coordinated by Miss Barbara K. Meier. The long tedious task of typing all these tables for the Third Edition on a word

processor was handled admirably by Mrs. Betty Clark and Mrs. Jan Crouch. Their patience, hard work, and talents are very much appreciated and will be long remembered.

10. Indices to Tables

There are two indices provided with this publication. Both indices are alphabetical, one by chemical name and one by chemical formula. In both cases the state of the compound is given in parentheses after the chemical formula. The tables and discussions are arranged in the same order as given in the chemical formula index.

10.1. Description of the Chemical Formula Index to the NIST-JANAF Thermochemical Tables

The tables included in this publication are ordered as given by the Chemical Formula Index. The modified Hill indexing system [J. Am. Chem. Soc. **22,** 478 (1900)] for chemical compounds, as used by Chemical Abstracts, is employed here to order the tables.

The Hill empirical formula is obtained for a particular compound by placing the elements in their alphabetical order unless C is present, in which case C is placed first, H second, and the remaining elements in alphabetical order. Substances with the same Hill formula are ordered alphabetically by their name. However, tables representing different states of the same species are in the order crystal, liquid, crystal-liquid, and ideal gas.

As examples, BeCl(g) would appear as written, whereas NaCl(g) would be filed under ClNa(g). To expand on the ordering of carbon compounds, the C always comes first, followed immediately by H if hydrogen is present, and then followed by any other elements present in their normal alphabetical order. The number of atoms of the element indexed first also influences the order of indexing the compound; e.g., all formulas with C (one carbon atom only) come before those with C_2 (two carbon atoms), followed by C compounds, and so on. Thus: $CHBF_4O$ (formyl fluoride, compound with BF_3), $CHCl_3$ (chloroform), CH_2F_3P (trifluormethylphosphine), CH_3NO_3 (methyl nitrate), CH_4Cl_2Si (dichloromethylsilane), $CH_{10}N_4O_3$ (hydrazine carbonate), CO (carbon monoxide), CO_2 (carbon dioxide), CO_3Zn (zinc carbonate), CZr (zirconium carbide), C_2Ba (barium acetylide), C_2BrClF_2 (bromochlorodifluoroethylene), C_2Ca (calcium carbide), and so on. See any formula index of Chemical Abstracts for further details and examples.

The electron gas, e^- (ref st), is inserted in the filing order after the deuterium species. Nonstoichiometric compounds are inserted just prior to or just after the corresponding stoichiometric order.

10.2. Description of the Chemical Name Index to the NIST-JANAF Thermochemical Tables

The nomenclature for the chemical species included in this publication does not fully correspond to the current Chemical Abstracts practice. The attempt has been made to use names as easily understandable as possible while not deviating far from the Chemical Abstracts system. Cited are two examples where the Chemical Abstracts nomenclature is followed, $AlBr_3(g)$ and $BBr_3(g)$ are listed as aluminum bromide and tribromoborane, respectively. For historical reasons, we would have preferred to name $BBr_3(g)$ as boron bromide. However, Chemical Abstracts refers to most boron halides as borane derivatives. On the other hand, whereas Al_2Br_6 is called di-μ-bromotetrabromoaluminum in Chemical Abstracts, this publication uses aluminum bromide.

In summary, general comments on the nomenclature are:

(1) The carbon and silicon neutral species follow the Chemical Abstracts organic-type nomenclature in which the name reflects the type of bonding.

(2) The -ium suffix that denotes positive ions is not used. $CH^+(g)$ is named 'methylidyne, ion' whereas Chemical Abstracts uses methyliumylidene.

(3) Salts are not named as an acid, metal salt of. For example, $BaSO_4$ is barium sulfate, not sulfuric acid, barium salt.

(4) Many mineral names are used.

(5) The sometimes confusing nomenclature for bridged structures in dimers is not used. Normally the monomer name is used.

In adopting this modified Chemical Abstracts nomenclature, there are numerous species for which the name will be significantly different from earlier JANAF publications. It is impractical to list all name changes, but in the more severe cases, a comment is made on the tables as to the previously used name.

10.3 Chemical Formula Index

Formula	Table Title	Page
Al_1(ref)	Aluminum (Al)	59
Al_1(cr)	Aluminum (Al)	60
Al_1(l)	Aluminum (Al)	61
Al_1(cr,l)	Aluminum (Al)	62
Al_1(g)	Aluminum (Al)	63

PREVIOUS: June 1979 (1 atm) CURRENT: June 1983 (1 bar)

$S°(298.15\ K) = 28.275 \pm 0.08\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 933.45 \pm 0.01\ K$

$\Delta_f H°(0\ K) = 0\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = 0\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 10.711 \pm 0.21\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Zero by definition.

Heat Capacity and Entropy

The adopted thermal functions for Al(cr) are derived from the studies of Giauque and Meads,[1] Berg,[2] Downie and Martin,[3] Takahashi,[4,5] McDonald,[6] Brooks,[7] Pochapsky[8] and Ditmars *et al.*[9] The mathematical and graphical treatment of these eight studies yields a continuous and smooth heat capacity curve. In contrast, CODATA[9] has recommended an $S°(298.15\ K)$ value which is $0.075\ J \cdot K^{-1} \cdot mol^{-1}$ greater than ours. Their result was based on an analysis of the low temperature heat capacity data of Giauque and Meads[1] and Berg.[2] At the time of their analysis, the studies of Downie and Martin[3] and Takahashi[4,5] had not been published. The three more recent studies[3,4,5,8] suggest a lower heat capacity in the vicinity of 298.15 K, thus the lower entropy in comparison with CODATA.[10]

Roberts[11] surveyed the superconductive properties of the elements and recommended a critical temperature of 1.175 ± 0.002 K for Al(cr). Since this temperature is so low, the effects of superconductivity on the thermodynamic functions are not considered. The entropy contribution due to superconductivity will be less than $0.002\ J \cdot K^{-1} \cdot mol^{-1}$. The data of Giauque and Meads[1] and Downie and Martin[3] agree at temperatures up to 150 K but drift apart by $0.2\ J \cdot K^{-1} \cdot mol^{-1}$ at 200 K and $0.17\ J \cdot K^{-1} \cdot mol^{-1}$ at 300 K, with the Downie and Martin study being lower. The Takahashi[4,5] study is even lower at ~298 K. The high temperature heat capacity values are derived from the enthalpy study of Ditmars *et al.*[9] Their curve is intermediate between those derived from previous studies[4,5,6,7,8] and implies a flatter C_p curve near the melting point (in comparison to previous interpretations). Numerous other heat capacity and enthalpy studies are available but were omitted in this analysis. A detailed discussion of the Group IIIA metals (B, Al, and Ga) is in preparation by the JANAF staff.

Fusion Data

Refer to the liquid table for details.

Sublimation Data

There are no sublimation studies for Al(cr). The adopted value of $\Delta_{sub} H°(298.15\ K)$ is the value recommended by CODATA.[10] Refer to the ideal gas table for details.

$S°(298.15\ K) = [39.549]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 933.45 \pm 0.01\ K$

$\Delta_f H°(298.15\ K) = [10.562]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 10.711 \pm 0.21\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of formation of liquid aluminum is calculated from that of the crystal by adding $\Delta_{fus}H°$ and the difference in enthalpy, $H°(933.45\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The adopted heat capacity values are derived from the enthalpy study of McDonald.[1] The enthalpy data, ten experimental points in the liquid region (941–1647 K), were measured in crucibles of BN and TiB_2 sealed in a platinum–rhodium capsule. This containment procedure reduced the problem with the reactivity of liquid aluminum. This data suggests a constant liquid heat capacity of 7.589 $cal·K^{-1}·mol^{-1}$ for this 700 K range.

The liquid enthalpy data of Awbery and Griffiths,[2] four points in the liquid region (937–1036 K), agree within 1% with our adopted enthalpy values. The enthalpy studies of Wust *et al.*[3] and Umino[4] are lower by as much as 4% and 12%, respectively. The heat capacity values of Schmidt *et al.*,[5] 17 values in the range 933–1300 K, are not constant but lie 6–11% lower than our adopted values.

Fusion Data

There are numerous enthalpy of fusion studies reported in the literature. Twelve studies [1-3, 5-13] reported values in the range 2.46 to 2.66 $kcal·mol^{-1}$, with a rather isolated value at 2.15 $kcal·mol^{-1}$.[4] We adopt a value 2.560 ± 0.05 $kcal·mol^{-1}$ based on the enthalpy data of McDonald.[1] The chosen value has eliminated uncertainty due to reaction of liquid aluminum and its vessel by use of BN and TiB_2 containers.

The adopted melting temperature, T_{fus} = 933.45 K, is a secondary standard on IPTS–68.[14,15]

Vaporization Data

The vaporization studies are summarized on the Al(g) table. The boiling point (fugacity of one bar), T_{vap} = 2790.812 K, is calculated as the temperature for which $\Delta_f G° = 0$ for Al(l) ≈ Al(g). The difference in the enthalpy of formation of Al(l) and Al(g) at T_{vap} is the enthalpy of vaporization, $\Delta_{vap}H° = 294.001\ kJ·mol^{-1}$.

Enthalpy of Formation

The enthalpy of formation is derived from the vaporization measurements of Brewer and Searcy (1383–1468 K),[1] Porter *et al.* (932 K),[2] Potter and Hildenbrand (1400–1611 K),[3] Rao and Motzfeld (1556 K),[4] and Johnson *et al.* (1327 K).[5] The adopted value $\Delta_f H°$(Al, g, 298.15 K) = 78.8 ± 1.0 $kcal·mol^{-1}$ is that adopted by CODATA.[6] The difference in $S°$(Al, cr, 298.15 K) between our adopted value and that of CODATA[6] would create a change of only 0.02 $kcal^{-1}·mol^{-1}$in $\Delta_f H°$(Al, g, 298.15 K). Other vaporization studies have been omitted in this analysis: Farkas (1476 K)[7] Baur and Brunner (1734–2237 K),[8] and Priselkov *et al.* (1273–1473 K).[9]

Heat Capacity and Entropy

The electronic energy levels are given in the compilation by Martin and Zalubas.[10] Although we list only the ground state, the two lowest excited states, the highest observed excited state (below the ionization limit), and the ionization potential for Al(g), all levels below the ionization limit listed by Martin and Zalubas[10] are used in the calculation. The 105 observed levels below the ionization limit are too numerous to list completely. However, they include contributions from observed levels to n = 35. The contributions are from excitations of the 3p electron in the ground state configuration, $1s^22s^22p^63s^23p$. There is a contribution at ~29000 cm^{-1} due to the excitation of a 3s electron, giving rise to a $1s^22s^22p^63s3p^2$ configuration. Other contributions of this latter type lie above the ionization limit.

The electronic level at 112.061 cm^{-1} has a significant effect on the thermodynamic values at low temperatures. The higher electronic states have an effect on the values above 3000 K. The Gibbs energy function values up to 4000 K are essentially independent of the estimated missing levels (for n < 35), the cut-off procedure, and the inclusion of levels for n > 3.

The thermal functions at 298.15 K agree with recent CODATA recommendations[6] except for two minor differences. First, the entropy differs by 0.1094 $J·K^{-1}·mol^{-1}$ because this table uses a standard state pressure of 1 bar, whereas the CODATA recommendations are based on 1 atm. Second, an entropy difference of 0.004 $J·K^{-1}·mol^{-1}$ arises due to the use of slightly different values for the fundamental constants.

PREVIOUS: June 1979 (1 atm) CURRENT: June 1983 (1 bar)

IP(Al^+, g) = 151862.7 ± 0.4 cm^{-1}
$S°(298.15\ K)$ = 149.950 ± 0.04 $J·K^{-1}·mol^{-1}$

$\Delta_f H°(0\ K)$ = 904.86 ± 4.2 $kJ·mol^{-1}$
$\Delta_f H°(298.15\ K)$ = [912.713] $kJ·mol^{-1}$

Electronic Levels and Quantum Weights		
State	ϵ_i, cm^{-1}	g_i
$^1S_0$	0.00	1
$^3P_0$	37393.03	1
$^3P_1$	37453.91	3
$^3P_2$	37577.79	5
$^1P_1$	59852.02	3

Enthalpy of Formation

$\Delta_f H°(Al^+, g, 0\ K)$ is calculated from $\Delta_f H°(Al, g, 0\ K)$[1] using the spectroscopic value of IP(Al) = 48278.37 ± 0.02 cm^{-1}(577.538 ± 0.0002 $kJ·mol^{-1}$) from Martin and Zalubas.[2] The ionization limit is converted from cm^{-1} to $kJ·mol^{-1}$ using the factor 1 cm^{-1} = 0.01196266 $kJ·mol^{-1}$, which is derived from the 1973 CODATA fundamental constants.[3] Rosenstock *et al.*[4] and Levin and Lias[5] have summarized additional ionization and appearance potential data.

$\Delta_f H°(Al^+, g, 298.15\ K)$ is calculated from $\Delta_f H°(Al, g, 0\ K)$ by using IP(Al) with JANAF[1] enthalpies, $H°(0\ K) - H°(298.15\ K)$, for Al(g), $Al^+(g)$, and e^-(ref). $\Delta_f H°(Al \rightarrow Al^+ + e^-, 298.15\ K)$ differs from a room temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[4] $\Delta_f H°(298.15\ K)$ should be changed by −6.197 $kJ·mol^{-1}$ if it is to be used in the ion convention that excludes the enthalpy of the electron.

Heat Capacity and Entropy

The information on electronic energy levels and quantum weights, given by Martin and Zalubas,[2] is incomplete because many theoretically predicted levels have not been observed. Our calculations indicate that any reasonable method of filling in these missing levels and cutting off the summation in the partition function[6] has no effect on the thermodynamic functions to 6000 K. This is a result of the high energy of all levels other than the ground state and the first four excited states; the next excited state is 85481.35 cm^{-1} above the ground state. Since inclusion of these excited states has no effect on the thermodynamic functions (to 6000 K), we list only the ground state and the first four excited states. The reported uncertainty in $S°(298.15\ K)$ is due to uncertainties in the relative ionic mass and the fundamental constants. Extension of these calculations above 6000 K may require consideration of the excited states and use of different fill and cutoff procedures.[6]

$^1D_2$	2678	5

Enthalpy of Formation

$\Delta_f H°(Al^-, g, 0 K)$ is calculated from $\Delta_f H°(Al, g, 0 K)$[1] using the adopted election affinity of EA(Al) = 0.441 ± 0.010 eV (42.550 ± 0.965 kJ·mol^{-1}). This value, recommended by Hotop and Lineberger[2] is based on a laser photodetachment electron spectrometry study.[3] Additional information on $Al^-(g)$ may be obtained in the critical discussions of Hotop and Lineberger,[2, 4] Rosenstock *et al.*[5] and Massey.[6]

$\Delta_f H°(Al^-, g, 298.15 K)$ is obtained from $\Delta_f H°(Al, g, 0 K)$ by using EA(Al) with JANAF[1] enthalpies, $H°(0 K)-H°(298.15 K)$, for $Al^-(g)$, Al(g), and e^-(ref). $\Delta_r H°(Al^- \rightarrow Al + e^-, 298.15 K)$ differs from a room-temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[5] $\Delta_f H°$(298.15 K) should be changed by + 6.197 kJ·mol^{-1} if it is to be used in the ion convention that excludes the enthalpy of the electron.

Heat Capacity and Entropy

The ground state electronic configuration for $Al^-(g)$ is given by Hotop and Lineberger,[2, 4] Rosenstock *et al.*[5] and Massey.[6] The fine-structure separation has been calculated via an isoelectronic extrapolation of ratios of fine structure separations[4] and is that recommended by Hotop and Lineberger.[2]

A comparison of the isoelectronic sequence – $Al^-(g)$, Si(g), $P^+(g)$, and $S^{++}(g)$ – would suggest that two states, $^1D_2$ and $^1S_0$, may exist at low wave numbers. Feigirle *et al.*[3] using laser photodetachment electron spectrometry, observed the bound state, $^1D_2$, at 0.332 eV. The $^1S_0$ state would correspond to a metastable state.

Ground State Quantum Weight: [1] $\sigma = 1$

Point Group: [C_s]

Bond Distances: Al–O = [1.66] Å; O–B = [1.36] Å; B=O = [1.20] Å

Bond Angles: Al–O–B = [145]°; O–B=O = [180]°

Product of the Moments of Inertia: $I_A I_B I_C = [6.527732] \times 10^{-115}\ g^3\ cm^6$

Enthalpy of Formation

The enthalpy of formation, $\Delta_f H°(AlBO_2, g, 298.15\ K) = -129.4 \pm 4$ kcal·mol^{-1} is calculated from the enthalpy of reaction, $\Delta_r H°(1500\ K) = -14.7 \pm 3.2$ kcal·mol^{-1} for 1/2 $Al_2O(g)$ + 1/2 $B_2O_3(g)$ = $AlBO_2(g)$ with all JANAF auxiliary data. The value of $\Delta_r H°(1500\ K)$ was obtained from the mass spectrometric determination of ion intensity ratios by Buchler *et al.*[1]

Heat Capacity and Entropy

The bent molecular structure, the bond distances O–B and B=O, and the bond angle O–B–O are assumed to be the same as those in $LiBO_2(g)$. The bond distance Al–O and the bond angle Al–O–(BO) are estimated to be the same as those in $Al_2O(g)$. The principal moments of inertia are $I_A = 0.7404 \times 10^{-39}$, $I_B = 29.3249 \times 10^{-39}$, and $I_C = 30.0653 \times 10^{-39}$ g cm^2.

The vibrational frequencies were estimated by comparison with those in $LiBO_2(g)$, $Al_2O(g)$, $B_2O_3(g)$, and AlCl(g).

Enthalpy of Formation

Ram,[1] Gaydon,[2] Singh,[3] Rosen[4] and Barrow[5] reference possible spectroscopic values for the dissociation energy of AlBr(g). The $A^1\Pi$ state yielded three values for the dissociation energy: 106.9 kcal·mol^{-1} by a short extrapolation, a minimum of 104.4 kcal·mol^{-1} as indicated by the highest observed vibrational level, and a maximum of 105.7 kcal·mol^{-1} as determined by predissociation which sets in at $v' = 4$. Ram[1] has observed rotational predissociation in the AlBr band system and reports the dissociation energy at 105.85 ± 0.46 kcal·mol^{-1}. Gaydon[2] reports a value of 86.5 kcal·mol^{-1} based on a ground state linear Birge–Sponer extrapolation (v, 0–11). However, substituting the values tabulated above for ω_e and $x_e\omega_e$ into the equation $D° = \omega_e^2/4X_e\omega_e - 0.5\omega_e$, a value of 76.5 kcal·mol^{-1} is obtained for the dissociation energy. A value of 105 kcal·mol^{-1} is suggested by Barrow[5] based on wavelengths for maximum photoionization.

Semenkovich[6] measured the vapor pressure of the reaction Al(l) + NaBr(l) → Na(g) + AlBr(g) at 1175 K. By the 3rd law method $\Delta_f H°$(298.15 K) is equal to 108.134 kcal·mol^{-1}. Using JANAF auxiliary data,[7] $\Delta_f H°$(AlBr, g, 298.15 K) is equal to 3.829 kcal·mol^{-1} and the dissociation energy is 100.87 kcal·mol^{-1}.

Gross[8] studied the equilibrium involved in the reaction 2 Al(l) + $AlBr_3$(g) → 3 AlBr(g) in the range 550 − 1300°C. The reported $\Delta_f H°$(298.15 K) is 106.27 kcal·mol^{-1}. Using auxiliary JANAF data,[7] $\Delta_f H°$(298.15 K) is 4.43 kcal·mol^{-1} and $D_0°$ is 100.26 kcal·mol^{-1}.

It should be noted that the highest observed vibrational level in the $A^1\Pi$ state lies approximately 4 kcal·mol^{-1} above the thermochemical dissociation energy of Semenkovich[6] and Gross.[8] This suggests a potential maximum in the $A^1\Pi$ state as mentioned by Barrow.[5] A similar maximum is suggested for AlF(g) and AlCl(g).[7,9,5] In addition, Wyse and Gordy,[10] from nuclear quadrupole coupling, deduce that the ionic character of the AlBr bond is ≥8%. Thus the value of $D_0° = 76.5$ kcal·mol^{-1} as obtained by a linear Birge–Sponer extrapolation is undoubtedly too low.[2] This ground state extrapolation was adjusted to 99.5 kcal·mol^{-1} and 102.2 kcal·mol^{-1} using two ionic character correction factors as suggested by Hildenbrand.[9] The former value is more suitable for metal fluorides while the latter is for the more general case. A comparison of $D_0°$ values[7,2,4] for the group IIIA gaseous monohalides suggests a value of 96−103 kcal·mol^{-1}, which is consistent with the value obtained by Semenkovich[6] and Gross.[8]

Due to the high ionic character in the AlBr bond and the possible unreliability of extrapolations of excited states which contain a potential maximum, the spectroscopic data is suspect as to the determination of $\Delta_f H°$(298.15 K). The chosen value for $\Delta_f H°$(298.15 K), 15.90 kJ·mol^{-1}, is a rounded value from the vapor pressure work of Semenkovich.[6]

Heat Capacity and Entropy

The spectroscopic constants for $Al^{79}Br$ and $Al^{81}Br$ were taken from Wyse and Gordy[10] and averaged according to the natural isotopic abundance of bromine. The electronic states are taken from Rosen[4] with the exception of the upper $^3\Pi$ state and the $b^3\Sigma^+$ state. The upper $^3\Pi$ state is estimated to be approximately in a linear relationship with the two lower $^3\Pi$ state. The $b^3\Sigma^+$ state is assigned by analogy with AlF and AlCl.[7] Lakshminarayana and Haranath[11] also reported values for two of the $a^3\Pi$ states which are in excellent agreement with Rosen's values.[4]

$S°(298.15\ K) = 180.22 \pm 1.05\ J·K^{-1}·mol^{-1}$
$T_{fus} = 370.6 \pm 0.2\ K$

$\Delta_f H°(0\ K) = -491.90 \pm 0.84\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -511.28 \pm 0.84\ kJ·mol^{-1}$
$\Delta_{fus} H° = 11.25 \pm 0.84\ kJ·mol^{-1}$

Enthalpy of Formation

The value chosen for the enthalpy of formation is the weighted average of the direct combination value reported by Gross *et al.*[1] and the solution calorimetry value given by Efimov, Kislova and Medvedev.[2]

Gross, Hayman, and Stuart[1] measured calorimetrically the standard enthalpy of formation of $AlBr_3$(cr) at 25°C by reacting Al with liquid bromine in a glass combustion vessel. They reported $\Delta_f H°(AlBr_3, cr, 298.15\ K) = -122.16 \pm 0.10\ kcal·mol^{-1}$.

Efimov *et. al.*[2] measured the heat of solution of $AlBr_3$(cr) in an aqueous HCl solution containing KCl(cr) and the heat of solution of $AlCl_3$(cr) in an aqueous HCl solution containing KBr(cr). From these heats of solution measurements and using the heats of formation of $AlCl_3$(cr),[3] KCl(cr)[4,5] and KBr(cr)[4,6] as auxiliary data, they obtained $\Delta_f H°(AlBr_3, cr, 298.15\ K) = -122.5 \pm 0.5\ kcal·mol^{-1}$.

Anthony *et al.*[10] measured the heat of solution of $AlBr_3$(cr) and $AlCl_3$(cr) in an aqueous alkaline solution containing dissolved sodium halides. They reported $\Delta_f H°(AlBr_3, cr, 298.15\ K) = -118.3 \pm 0.6\ kcal·mol^{-1}$. Eley and Watts,[11] in studying heats of solution of $AlBr_3$ and its complexes with pyridine, trimethylamine, and triethylamine in HCl, reported $\Delta_f H°(AlBr_3,cr,298.15K) -125.6\ kcal·mol^{-1}$. Klemm and Tanke[12] measured the heat of solution of $AlBr_3$(cr) at 0°C in aqueous HCl. Using auxiliary data, including estimated heat capacities, Klemm and Tanke[11] reported $\Delta_f H°(AlBr_3, cr, 298.15\ K) = -121\ kcal·mol^{-1}$. Gross, Hayman, and Stuart[1] have re-examined the data of Klemm and Tanke[12] and have calculated $\Delta_f H°(AlBr_3, cr, 298.15\ K) = -122.4\ kcal·mol^{-1}$. This latter value was based on the heat of solution measurements,[13] $\Delta_f H°(AlCl_3, cr, 298.15\ K) = -168.65\ kcal·mol^{-1}$, and on the enthalpies of formation difference of chloride and bromide ions at the proper concentration.

A number of other studies on the enthalpies of formation of $AlBr_3$(cr) are based on solution calorimetry. The earliest measurements in water[7,8,9] are probably not reliable because of hydrolysis of the aluminum halide, but estimates of the enthalpy of formation of $AlBr_3$(cr) based on measurements in aqueous acid or base are also in disagreement.

Heat Capacity and Entropy

The heat capacities, 11.6 – 308 K, have been measured by Webb, Justice, and Prophet.[13] Above 308 K they are derived[13] from the enthalpy data measured by Fischer.[14] The entropy of the crystal is based on a value of $S°(12\ K) = 4.021\ J·K^{-1}·mol^{-1}$, as discussed in Webb *et al.*[13]

Fusion Data

Fischer[14] determined the melting temperature (T_{fus}) for $AlBr_3$(cr). The heat of melting ($\Delta_{fus}H°$) is calculated from the enthalpies of $AlBr_3$(cr) and $AlBr_3$(l) at the melting temperature. The enthalpy of the crystal at T_{fus} was determined from the curve use[l]uccircld for the heat capacity calculations. The enthalpy of the liquid at T_{fus} was determined from a linear least squares fit to the enthalpy data for $AlBr_3$(l) reported by Fischer.[14] See Webb *et al.*[13] for details.

Sublimation Data

The enthalpy of sublimation is calculated from the enthalpies of formation of the dimer and the crystal for the sublimation process, $2\ AlBr_3(cr) = Al_2Br_6(g)$, $\Delta_{sub}H°(298.15\ K) = +85.4 \pm 4.2\ kJ·mol^{-1}$. Also refer to the Al_2Br_6(g) table for additional comments.

$S°(298.15\ K) = [206.481]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 370.6 \pm 0.2\ K$

$\Delta_f H°(298.15\ K) = [-501.381]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 11.25 \pm 0.84\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(AlBr_3, l, 298.15\ K)$ is calculated from $\Delta_f H°(AlBr_3, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus} H°$, and the difference in enthalpy, $H°(370.6\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

Fischer[1] has measured the enthalpy of $AlBr_3(l)$ from 374 K to 406 K. The heat capacity is derived from a linear least squares fit to his data. The resulting constant value for the heat capacity is adopted for temperatures above 400 K.

$S°(AlBr_3, l, 298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

Refer to the crystal table for details.

Vaporization Data

Refer to the $Al_2Br_6(g)$ table for details.

Enthalpy of Formation

Fischer, Rahlfs, and Benze[1] have determined the equilibrium constants for the reaction $Al_2Br_6(g) = 2\ AlBr_3(g)$ from vapor density measurements. The heats of reaction are calculated from these data using both 2nd law and 3rd law methods. The results of the calculations are as follows, where the $\Delta_fH°(298.15\ K)$ is based on the 3rd law value of $\Delta_rH°(298.15\ K)$, for the reaction as written above, and $\Delta_fH°(Al_2Br_6, g, 298.15\ K) = -224.0\ kcal \cdot mol^{-1}$.

T/K	Data Points	$\Delta_rH°(298.15\ K)$, $kcal \cdot mol^{-1}$ 2nd law	Al_2Br_6 3rd law	Drift $cal \cdot K^{-1} \cdot mol^{-1}$	$\Delta_fH°(298.15\ K)$ $kcal \cdot mol^{-1}$
613–846	4	29.6 ± 1.0	27.78 ± 0.6	−2.6 ± 1.3	−98.11
605–854	7	29.4 ± 0.5	27.73 ± 0.5	−2.2 ± 0.7	−98.14

The adopted value for the enthalpy of formation is $\Delta_fH°(AlBr_3, g, 298.15\ K) = -98.1 \pm 0.4\ kcal \cdot mol^{-1} (-410.45 \pm 1.7\ kJ \cdot mol^{-1})$.

Heat Capacity and Entropy

Beattie and Horder[2] studied the gas phase Raman spectra of monomeric $AlBr_3$. The results are consistent with a planar structure of D_{3h} symmetry with $\nu_1 = 228\ cm^{-1}$(polarized) and $\nu_4 = 93\ cm^{-1}$. The weak antisymmetric stretching mode was tentatively assigned as $\nu_3 = 360\ cm^{-1}$.

Pong *et al.*,[3] in examining the infrared spectrum of the monomeric $AlBr_3$ isolated in solid argon, reported $\nu_2 = 155.0\ cm^{-1}$, $\nu_3 = 510\ cm^{-1}$ and $\nu_4 = 92\ cm^{-1}$ for $AlBr_3$ isolated in xenon.

The adopted values for ν_1 and ν_4 are taken from Beattie and Horder[2] while ν_2 and ν_3 are taken from Pong *et al.*[3] The Al–Br bond distance was estimated by Heise and Weiland[5] and is consistent with the trend of experimentally known bond distances in the gaseous molecules AlF_3, $AlCl_3$, and AlI_3.[6] The principal moments of inertia are $I_A = I_B = 102.5575 \times 10^{-39}$, and $I_C = 205.1151 \times 10^{-39}\ g \cdot cm^2$.

Enthalpy of Formation

Equilibrium constants as a function of temperature for the reaction 2 Al(l) + $AlCl_3$(g) → 3 AlCl(g) have been reported by many investigators. The heats of reaction are calculated from these data using second and third law methods. Unfortunately, most of the data are very discordant and of no help in defining $\Delta_f H°$(AlCl, g, 298.15 K). The results of Rao and Dadape[1] cover a temperature range of 300 K, show good compatibility with the thermodynamic functions, are near an average of all the data, and are judged most acceptable. The third-law heat of reaction derived from their data is adopted and combined with the heat of formation of $AlCl_3$(g)[12] to give $\Delta_f H°$(AlCl, g, 298.15 K) = −12.30 ± 1.5 kcal·mol^{-1} (−51.46 ± 6.3 kJ·mol^{-1}).

[a]Temperature range too small for significant second law calculation.
[b]Individual points not reported; calculation based on reported equation at extremes of temperature range cited.

Gross *et al.*[3] and Pinchuk *et al.*[8] have studied the reaction of sodium and potassium chloride with liquid aluminum to form aluminum monochloride. These studies lead to $\Delta_f H°$(298.15 K) values for AlCl(g) in the range of −12.69 ± 1.0 to −13.60 ± 1.5 kcal·mol^{-1}.

The adopted enthalpy of formation yields a dissociation energy of 498.57 kJ·mol^{-1} for AlCl(g). Barrow[13] and Ram[14] reference possible spectroscopic values for the dissociation energy. A short extrapolation of vibrational levels yields $D_0° = 519.2$ kJ·mol^{-1} but Barrow[13] speculates that a potential maximum in the A^1 state of AlF and AlCl causes extrapolation of levels to give erroneous heats of dissociation. Ram *et al.* has observed rotational predissociation in the AlCl bond system and reports the dissociation energy at 507.5 ± 0.97 kJ·mol^{-1}. This yields $\Delta_f H°$(AlCl, g, 298.15 K) = −60.42 kJ·mol^{-1} in reasonable agreement with the selected value.

Heat Capacity and Entropy

The spectrum of AlCl has been observed and analyzed by a number of investigators.[14,15,16,17] The spectroscopic constants for $Al^{35}Cl$ and $Al^{37}Cl$ are taken from the microwave study of Wyse and Gordy[17] and averaged according to the natural isotopic abundance of chlorine. The electronic levels are those reported by Sharma;[18] the value for the $b^3\Sigma^+$ state is somewhat uncertain. The assignment of electronic states is supported by theoretical calculations.[19]

Enthalpy of Formation

We adopt $\Delta_f H°(0\ K) = 204.5 \pm 10\ kcal·mol^{-1}$ based on that of AlCl(g)[1] combined with the ionization potential IP(AlCl) = 9.4 ± 0.4 eV (216.8 ± 9 $kcal·mol^{-1}$). IP(AlCl) is assumed to be equal to the electron–impact appearance potential of $AlCl^+$ measured as 9.4 ± 0.4,[2] 9.5 ± 0.3[3] and 9.3 ± 0.6 eV.[4] Theoretical values include IP = 8.83 eV from an extended Huckel calcualtion[5] and from ab initio calculations[6,7] either 8.4 eV (direct value) or 9.8 eV derived from $D_0°(AlCl^+)$. Electron–impact formation of $AlCl^+$ from $AlCl_3$[8] apparently yields fragment ions with excess energy; i.e., we derive the upper limit IP<11.7 eV.

For the dissociation process $AlCl^+(X^2\Sigma) \rightarrow Al^+(^1S) + Cl(^2P)$, our adopted $\Delta_f H°$ yields $D_0°(AlCl^+) = 39 \pm 10\ kcal·mol^{-1}$. This compares with $-31\ kcal·mol^{-1}$ derived from the theoretical potential energy curve[6,7] which, however, has a maximum of $-8\ kcal·mol^{-1}$ arising from an avoided crossing with another $^2\Sigma$ state.

Heat Capacity and Entropy

Bonding in Group III monohalides and their ions was characterized by Berkowitz and Dehmer[7] from photoelectron spectra and theoretical calculations.[6,7] They concluded that ionization removes an electron from an antibonding orbital centered mainly on the metal. This shortens the bond length and enhances the ionic nature of the bond. A decrease in bond length is observed for BF^+,[9] predicted for AlF^+[1] from Rydberg states of AlF, and predicted for $AlCl^+$ from theoretical calculations.[6,7]

For $AlCl^+$, we adopt r_e = 2.05 Å based mainly on the theoretical prediction.[6,7] This may be compared with 2.13 Å for AlCl and 2.06 Å for $AlCl_3$.[1] Lacking data for Rydberg states of AlCl, we estimate ω_e from $k(AlCl^+)/k(MgCl) = 1.7$ transferred from the similar isoelectronic pair AlF^+ and MgF.[1] B_e is calculated from r_e, while α_e and $\omega_e x_e$ are estimated by comparison with AlF^+, AlF and AlCl.[1]

The electronic ground state and an approximate value for the $^2\Pi$ level are based on theoretical calculations.[6,7] These suggest that $^2\Pi$ has only a shallow minimum (r_e>3.6 Å) or possibly is repulsive. They also indicate the presence of a $^2\Sigma$ state having a double minimum above 30000 cm^{-1}. We include only the $^2\Pi$ state. If it is repulsive, our thermodynamic functions are upper–limit values. The bias would be quite small even at 3000 K.

Enthalpy of Formation

We tentatively adopt $\Delta_f H°(298.15\ K) = -117 \pm 15\ kcal \cdot mol^{-1}$ and $\Delta_{at} H°(0\ K) = 241 \pm 15\ kcal \cdot mol^{-1}$ based on our average bond energies for $AlF_2(g)$ and $AlCl_2(g)$.[1] Mass-spectrometric data[2,3] yield $\Delta_f H°(298.15\ K) = -142.6$ and $\Delta_{at} H°(0\ K) = 267\ kcal \cdot mol^{-1}$, corresponding to an enhancement of 26 $kcal \cdot mol^{-1}$ in the stability of AlClF(g). The same study[2,3] indicated stability enhancements of 22 (or 13) $kcal \cdot mol^{-1}$ for AlF_2, 19 $kcal \cdot mol^{-1}$ for $AlClF_2$, and 22 $kcal \cdot mol^{-1}$ for $AlCl_2F$. See the appropriate tables[1] for further details.

Farber *et al.*[2,3] used molecular flow effusion of vapors of AlF_3 and $AlCl_3$ over Al(l) in Al_2O_3(cr) to study the reaciton Al-Cl(g) + AlF(g) = AlClF(g) + Al(g). They calculated *Kp* (5 points, 1338–1537 K) directly from mass-spectrometric ion intensities. Using JANAF auxiliary data,[1] we derive $[\Delta_r S°(2nd\ law) - \Delta_r S°(3rd\ law)] = 0.8 \pm 18\ cal \cdot K^{-1} \cdot mol^{-1}$, $\Delta_f H°(298.15\ K) = 12 \pm 25$ (2nd law) or 11.2 ± 5 (3rd law) and $\Delta_f H°(298.15\ K) = -142.6 \pm 5\ kcal \cdot mol^{-1}$. These results are internally consistent but, as in the case of AlF_2,[2,3] we suspect that common problems may cause a negative bias in $\Delta_f H°$. The ionizing energy is ambiguous: 20 eV[3] or AP + 3 eV.[2] The appearance potential $AP(AlClF^+) = 11 \pm 1$ eV is biased by ~2 eV, raising several questions about interpretation of the data (see $AlCl_2^+$).[1] It is conceivable that $AlClF^+$ arises from a process other than direct ionization of AlClF.

We conclude from these speculations that the experimental data[2,3] are insufficient to establish the enhanced stability of AlClF. Mass-spectrometric data indicate very little enhanced stability in BClF,[4] in agreement with average bond energies summarized on the table for $AlCl_2$.[1]

Heat Capacity and Entropy

The electronic ground state, excited levels, bond distances and bond angle are assumed to be the same as in $AlCl_2$ and AlF_2.[1] Vibrational frequencies are estimated by comparison with $AlCl_2$ and AlF_2.[1] The principal moments of inertia are $I_A = 2.3419 \times 10^{-39}$, $I_B = 23.6618 \times 10^{-39}$ and I_C 26.0037×10^{-39} $g \cdot cm^2$.

Ground State Quantum Weight: [1] $\sigma = 1$
Point Group: $[C_{\infty v}]$
Bond Distances: Al–F = [1.60] Å; Al–Cl = [2.05] Å
Bond Angle: F–Al–Cl = [180]°
Rotational Constant: $B_o = [0.095960]\ cm^{-1}$

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = 66 \pm 30\ kcal \cdot mol^{-1}$ based on $\Delta_f H°$ of AlClF[1] combined with the ionization potential IP(AlClF) = 182 ± 23 $kcal \cdot mol^{-1}$ (7.9 ± 1 eV). IP is estimated by comparison with $IP(AlCl_2) = 7.8 \pm 0.9$ eV and $IP(AlF_2) = 8.1 \pm 0.9$ eV.[1] Farber and Harris[2] reported an appearance potential of $AP(AlClF^+) = 11 \pm 1$ eV which appears to be seriously biased. This is discussed on the tables for $AlCl_2^+(g)$ and AlClF(g).

Heat Capacity and Entropy

We assume the electronic ground state to be linear $^1\Sigma^+$ and neglect excited states.[1] Bond distances are estimated to be the same as in $AlCl_2^+$ and AlF_2^+.[1] Vibrational frequencies are estimated by comparison with AlClF, $AlCl_2^+$ and AlF_2^+.[1]

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -238.8 \pm 1.5\ kcal \cdot mol^{-1}$ and $\Delta_{at} H° = 380.8 \pm 3\ kcal \cdot mol^{-1}$ based on $\Delta_f H°(298.15\ K) = 0.5 \pm 1\ kcal \cdot mol^{-1}$ for 1/3 $AlCl_3(g)$ + 2/3 $AlF_3(g)$ = $AlClF_2(g)$. Krause and Douglas[1] obtained this result by an entrainment method which measured enhanced volatility of AlF_3 in the presence of $AlCl_3$. Corrections were made for all the possible dimers which can form in this system. The entrainment data establish that aluminum fluoride–chloride exchange reactions are almost thermoneutral.

Our adopted $\Delta_f H°$ is compared below with an approximate mass–spectrometric K_p for reaciton of AlF_2 with $AlCl_2$.[2] The discrepancy in $\Delta_f H°(AlClF_2)$ is −19 $kcal \cdot mol^{-1}$ if we use $\Delta_f H° = -180$ (AlF_2) and −71 ($AlCl_2$) derived from the mass–spectrometric data.[2, 3] The discrepancy disappears if we use $\Delta_f H° = -166$ (AlF_2) and −67 ($AlCl_2$) derived from average bond energies in AlF_3 and $AlCl_3$.[4] This favors the latter values of $\Delta_f H°$ for AlF_2 and $AlCl_2$,[4] although the discrepancy might arise from the observed ion intensity of $AlClF_2^+$. The signal from $AlClF_2^+$ was very weak at 40 eV;[5] this high ionizing energy might bias K_p and cause considerable fragmentation. We can eliminate AlF_2 and $AlCl_2$ by taking the difference between the mass–spectrometric reactions for $AlClF_2$ and $AlCl_2F$.[4] *This yields* $[\Delta_f H°(AlClF_2) - \Delta_f H°(AlCl_2F)] = -47\ kcal \cdot mol^{-1}$ which agrees with $-49.8\ kcal \cdot mol^{-1}$ from entrainment data.[1] Thus, we tentatively ascribe the discrepancy to AlF_2[4] and $AlCl_2$.

Source	Method	Reaction	T/K	$\Delta_r H°(T)$	$\Delta_f H°(298.15\ K)$		$\Delta_f H°(298.15\ K)$

[a]Assuming $\Delta_f H°(298.15\ K) = -166$ (AlF_2) and −67 ($AlCl_2$) $kcal \cdot mol^{-1}$
[b]Assuming $\Delta_f H°(298.15\ K) = -180$ (AlF_2) and −71 ($AlCl_2$) $kcal \cdot mol^{-1}$

Heat Capacity and Entropy

We adopt a C_{2v} structure with bond angles and bond distances assumed equal to those in AlF_3 and $AlCl_3$.[4] We assume a singlet electronic ground state and neglect excited states. Vibrational frequencies are estimated by comparison of AlF_3 and $AlCl_3$ with the series BF_3, $BClF_2$, BCl_2F and BCl_3.[6, 7] The principal moments of inertia are $I_A = 12.5730 \times 10^{-39}$, $I_B = 26.2481 \times 10^{-39}$, and $I_C = 38.8212 \times 10^{-39}\ g \cdot cm^2$.

$S°(298.15\ K)$ = [54.4 ± 4] $J·K^{-1}·mol^{-1}$
T_{fus} = Unknown
T_{dcm} = [500] K

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -793.3 \pm 1.3\ kJ·mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

$\Delta_f H°$(AlOCl, cr, 298.15 K) is calculated from $\Delta_r H°(298.15\ K) = 21.05\ kcal·mol^{-1}$ for the reaction $AlOCl(cr) + Cl_2(g) = AlCl_3(cr) + 1/2\ O_2(g)$ reported by Schafer *et al.*[1] This reaction is the overall reaction of the following four separate reactions:

Reaction	$\Delta_r H°(298.15\ K)$, $kcal·mol^{-1}$
$AlOCl(cr) + 2(HCl 299.5\ H_2O) = AlCl_3·600\ H_2O(l)$	−46.9
$AlCl_3·600\ H_2O(l) = AlCl_3(cr) + 600\ H_2O(l)$	+79.3
$H_2O(l) = H_2(g) + 1/2\ O_2(g)$	+68.32
$H_2(g) + Cl_2(g) + 599\ H_2O(l) = 2(HCl·299.5\ H_2O)$	−79.67
$AlOCl(cr) + Cl_2(g) = AlCl_3(cr) + 1/2\ O_2(g)$	+21.05

Heat Capacity and Entropy

The heat capacities for AlOCl(cr) are estimated based on the assumption that $\Delta C_p = 0$ for the reaction $AlCl_3(cr) + Al_2O_3(cr) = 3\ AlOCl(cr)$. $S°(298.15\ K) = 13\ cal·K^{-1}·mol^{-1}$ was estimated by Schafer *et al.*[1]

Decomposition Data

T_{dcm} is calculated as the temperature at which the Gibbs energy change of the reaction $6\ AlOCl(cr) \rightarrow 2\ Al_2O_3(cr) + Al_2Cl_6(g)$ is zero.

Ground State Quantum Weight: [1] $\sigma = 1$
Point Group: $C_{\infty v}$
Bond Distance: O–Al = [1.62] Å; Al–Cl = [2.14] Å
Bond Angle: O–Al–Cl = 180°
Rotational Constant: B_o = [0.097704] cm^{-1}

Enthalpy of Formation

The Gibbs energy change of the reaction 1/3 Al_2O_3(l) + 1/3 $AlCl_3$(g) = AlOCl(g), $\Delta_r G°(2400\ K) = 28 \pm 3\ kcal \cdot mol^{-1}$, has been determined by Greenbaum *et al.*[1] Incorporating appropriate auliliary data, the enthalpy of reaction is derived to be 82.9 $kcal \cdot mol^{-1}$, yielding $\Delta_f H°$(AlOCl, g, 298.15 K) = $-82.2 \pm 5\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

Point group, ground state quantum weight and vibrational frequencies are obtained from Hilsenrath *et al.*[2] The bond distances of r(O–Al) and r(Al–Cl) are assumed to be the same as those in AlO(g) and AlCl(g) molecules, respectively. The three principal moments of inertia are: $I_A = 0$ and $I_B = I_C = 2.86467 \times 10^{-38} g \cdot cm^2$.

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -67 \pm 5$ kcal·mol^{-1} and $\Delta_{at}H° = 201.4 \pm 6$ kcal·mol^{-1}; i.e., the average bond energy $\Delta_{at}H°/2 = 101$ kcal·mol^{-1} is taken equal to that of $AlCl_3$.[1] $\Delta_f H°$ is consistent with experimental results of -66 ± 3[2] and $\geq -71 \pm 5$ kcal·mol^{-1} [3,4] but there may be significant bias in these values.

Chai *et al.*[2] derived $\Delta_f H°(298.15\ K) = -66 \pm 3$ kcal·mol^{-1} from study of reactions of Al(c,l) with the vapor of $AlCl_3$ in an argon carrier gas. Weight–loss data (800–1000 K) for Al and $AlCl_3$ were analyzed assuming five vapor species (AlCl, $AlCl_2$, $AlCl_3$, Al_2Cl_4, Al_2Cl_6) in four simultaneous equilibrium reactions. Experimental data were combined with auxiliary data, including $S°(AlCl_2)$ and K_p for two reactions, to derive $\Delta_f H°(AlCl_2)$ and K_p for another reaction involving Al_2Cl_4. Despite minor changes in $S°(AlCl_2)$, $\Delta_f H° = -66$ is till appropriate for the $AlCl_2$ equilibrium.[2] We suspect, however, that this equilibrium is strongly dependent on the other equilibria, particularly that involving Al_2Cl_4(g).

Farber and Harris[3,4] reported K_p (5 points, 1150–1430 K) for the reaction $AlCl(g) + AlCl_3(g) = 2\ AlCl_2(g)$. We obtain $[\Delta_r S°(2nd\ law) - \Delta_r S°(3rd\ law)] = -35 \pm 10$ cal·K^{-1}·mol^{-1}, $\Delta_f H°(298.15\ K) = -36 \pm 13$(2nd law) or 10.5 ± 9(3rd law) and $\Delta_f H°(298.15\ K) \geq -70.7 \pm 5$ kcal·mol^{-1}. We consider $\Delta_f H°$ to be a negative limit due to possible bias arising from the ionizing energy. Energy of the ionizing electrons was variously reported as 20 eV[4] or as 3 eV above the AP.[3] If 20 eV was used, we expect $AlCl_2^+$ to be enhanced due to fragmentation of $AlCl_3$. The alternative ionizing energy leads to another problem, since the authors[3,4] used literature values for the AP of $AlCl^+$ but their own value for $AlCl_2^+$. Their value has a bias of −3 eV which is discussed in detail on the table for $AlCl_2^+$(g).[1] We suspect that the mass spectrometer had a biased energy scale during the measurments.[3,4] This would induce negative bias in the ionizing energy used for $AlCl^+$ and $AlCl_3^+$, since the AP's were not based on the experimental energy scale. Again we expect $AlCl_2^+$ to be enhanced relative to $AlCl^+$ and $AlCl_3^+$. The large discrepancy in $\Delta_r S°$ is symptomatic of a temperature–dependent error; we expect that bias in K_p is greatest at low T. NO_2, and NO. Although $[BE(MX)–BE(MX_3)] = -20$ kcal·mol^{-1}, only the mass–spectrometric data of Farber *et al.*[3–6] yield $BE(MX_2) > BE(MX_3)$. Other data[1,2,7] and theoretical calculations[8] suggest that $BE(MX_2) \leq BE(MX_3)$.

Heat Capacity and Entropy

The electronic ground state and excited levels are assumed to be the same as in AlF_2.[1] Vibrational frequencies are calculated from the estimated force constants $f_r = 2.2$ and $f_{rr}/r^2 = 0.13$ mdyn/Å. Frequencies and force constants are estimated from simultaneous consideration of $AlCl_2^+$, $AlCl_2$, $AlCl_2^-$ and the analogous boron species. We assume that frequency changes are qualitatively similar to those of NO_2^+, NO_2, and NO_2^-. Thus, in going from $AlCl_2^+$ to $AlCl_2$, we expect a large decrease in ν_3, an increase in ν_2 and a small increase in ν_1. By analogy with BF_2,[8] the odd electron of $AlCl_2$ should occupy an anti–bonding orbital which increases the bond length but decreases the bond angle and stretching force constant. We assume a bond length 0.05 Å longer than in $AlCl_2^+$ [1] and a bond angle equal to that in BF_2.[8] The principal moments of inertia are $I_A = 3.5781 \times 10^{-39}$, $I_B = 38.9438 \times 10^{-39}$ and $I_C = 42.5220 \times 10^{-39}$ g·cm^2.

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = 115 \pm 18$ kcal·mol^{-1} and $IP(AlCl_2) = 7.8 \pm 0.9$ eV. Electron–impact studies gave 13.4 ± 0.5 eV[1] and 13.4 ± 0.7 eV[2] for the appearance potential (AP) of $AlCl_2^+$ from $AlCl_3$. The analogous process for onset of BCl_2^+ from BCl_3 has been studied by both photoionization[3] and electron impact.[2] Comparison indicates that BCl_2^+ from electron impact[2] carried an excess energy (E*) of ~0.9 eV. We estimate the excess energy for $AlCl_2^+$ as 1.2 ± 0.6 eV. Thus, we take $AP–E^* = \Delta_f H° = 12.2 \pm 0.8$ eV (281.3 ± 18 kcal·mol^{-1}) for the reaction $AlCl_3(g) + e^-(g) = AlCl_2^+(g) + Cl(g) + 2\ e^-(g)$. With JANAF auxiliary data[4] this yields $\Delta_f H°(AlCl_2^+) = 113.5 \pm 18$, $\Delta_f H°(298.15\ K) = 115 \pm 18$ and $IP(AlCl_2) = 180 \pm 20$ kcal·mol^{-1} (7.8 ± 0.9 eV).

Electron impact studies[5–7] of $AlCl_2$ and BCl_2 gave approximate appearance potentials $AP(MCl_2^+) = 12 \pm 1$ eV. This is −4 eV greater than our adiabatic IP values. Such a difference could arise from several factors including bias in the ionizing–energy scale, bias in threshold detection, excess energy in MCl_2^+ and misassignment of the ionization process. The studies[5–7] make no mention of a calibrant gas for the energy scale. Reactive radicals (e.g. $AlCl_2$ from a reducing environment) may induce a bias in the energy scale. Consistent with this hypothesis, the values reported[6,7] for $AP(BCl^+/BCl)$ and $AP(BCl_2^+/BCl_3)$ are ~2 and 3–4 eV higher than other electron–impact data.[2,8] $AP(MCl_2^+/MCl_2)$ was obtained[5–7] by a vanishing current (or initial break) method. We expect this to have a positive bias which increases as the pressure of MCl_2 decreases.[9] Electron impact on MCl_2 should yield a vertical AP corresponding to a nonlinear (excited) configuration of MCl_2^+. Excitation energies of >1 eV are expected if MCl_2^+ is similar to BF_2^+ and AlF_2^+.[4] Alternatively, $AP(MCl_2^+) = 12 \pm 1$ eV[5–7] is a magnitude which may not exclude processes such as fragmentation or ion–molecular reactions of MCl_3. $AP(MCl_2^+)$ almost overlaps with the onset of MCl_2^+ from MCl_3; i.e., 12.30 eV[3] (photoionization) or 13.0−13.2 eV[2,8] (electron impact) from BCl_3 and 13.4 ± 0.5 eV[1,2] (electron impact) from $AlCl_3$. On the other hand, the coincidence of $AP(BCl^+) = AP(BCl_2^+) = 12 \pm 1$ eV[6,7] suggests that the two ions might be related, possibly via $BCl^+ + BCl_3 = BCl_2^+$. The authors[5,6] did not measure $AP(AlCl^+)$, but the analogous ion–molecular reaction is also energetically feasible. In summary, there are three plausible factors which may contribute to positive bias in the observed $AP(AlCl_2^+)$ and some conceivable alternative interpretations of the data.[5–7] This precludes use of $AP(AlCl_2^+)$ in calculating $\Delta_f H°$ of $AlCl_2^+$.

Hastie and Margrave[10] used an extended Hucket method to calculate $IP(AlCl_2) = 6.65$ eV. This result should approximate the vertical IP which we expect at ~9 eV.

Heat Capacity and Entropy

We assume the electronic ground state to be linear $^1\Sigma^+$ and neglect excited states by analogy with $MgCl_2$[4,11] and other tratomic species having sixteen valence electrons.[12] We estimate the bond distance to be almost the same as in $AlCl_3$ and 0.05 Å shorter than in $AlCl_2$.[4] 0 Likewise, we transfer the stretching force constant from $AlCl_3$ and the ratio $f_r/f_\alpha = 19$ Å^{-2} from $MgCl_2$.[11] Thus, we calculate vibrational frequencies from the estimated force constants $f_r = 2.9$, $f_{rr} = 0.2$ and $f_\alpha/r^2 = 0.036$ mdyn/Å. The resulting values have been rounded upward.

Point Group: $[C_{2v}]$ $\sigma = 2$
Bond Distance: Al–Cl = [2.15] Å
Bond Angle: Cl–Al–Cl = [105]°
Product of the Moments of Inertia: $I_A I_B I_C = [7.583526 \times 10^{-114}]\ g^3\ cm^6$

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -115 \pm 25\ kcal \cdot mol^{-1}$ based on an estimated electron affinity of $EA(AlCl_2) = 46 \pm 23\ kcal \cdot mol^{-1}$ (2.0 ± 1 eV) and a fluoride-ion affinity of $IA(AlCl) = 46 \pm 25\ kcal \cdot mol^{-1}$. JANAF auxiliary data[1] are used in converting from one quantity to another. If AlX_2 radicals were analogous to X atoms,[2,3] then $EA(AlCl_2)$ should be approximately equal to $EA(AlF_2) = 0.2 \pm 0.4$ eV.[1] This analogy may not be justified, since the pertinent orbitals are quite different. An electron added to AlX_2 presumably occupies a molecular orbital centered mainly on the metal opposite the two halogens. We assume that the orbital energy is characteristic of the metal Al and is perturbed relatively little by substitution of Cl for F. This implies that $EA(AlCl_2) \approx EA(AlF_2)$.

The energy for the self-ionization process, $2\ AlF_2 = AlF_2^+ + AlF_2^-$, is $\Delta_f H° = [IP(AlF_2) - EA(AlF_2)] = 5.9 \pm 1$ eV.[1] Assuming $AlCl_2$ is similar, we estimate $EA(AlCl_2) = 1.9$ eV. The energy difference between the reactions $AlF_2^- = AlF + F^-$ and $AlF_2 = AlF + F$ is $\Delta_r H° = [IA(AlF) - D_0°(AlF_2)] = -29\ kcal \cdot mol^{-1}$. Assuming $AlCl_2^-$ is analogous, we estimate $EA(AlCl_2) = 2.3$ eV. We adopt the intermediate value $EA(AlCl_2) = 2.0 \pm 1$ eV but emphasize that all estimates depend on AlF_2.[1]

Heat Capacity and Entropy

Electronic levels and quantum weights are assumed equal to those of isoelectronic $SiCl_2$[1] calculated from the estimated force constants $f_r = 1.73$, $f_{r\pi} = 0.07$ and $f_{\alpha}/r^2 = 0.156$ mdyn/Å. Frequencies and force constants are estimated from simultaneous consideration of $AlCl_2$, $AlCl_2$, $AlCl_2^-$ and the analogous boron species. We assume that frequency changes are qualitatively similar in the two series $AlCl_2^+$, $AlCl_2$, $AlCl_2^-$ and NO_2^+, NO_2, NO_2^-[1] which have the same number of valence electrons. Furthermore, we expect isoelectronic $SiCl_2$[1] to provide upper-limit frequencies for $AlCl_2^-$. Thus, in going from $AlCl_2$ to $AlCl_2^-$, we assume little change in ν_1 and ν_2 but a significant decrease in ν_3.

By analogy with BF_2,[4,5] we expect that the odd electron in $AlCl_2$ occupies a molecular orbital centered mainly on the metal opposite the two chlorides. This orbital should be antibonding[4] in the sense that addition of an electron increases the bond length but decreases the bond angle and stretching force constant. We assume that the bond length is 0.05 Å longer and the bond angle is 15° smaller than in $AlCl_2$.[1] The principal moments of inertia are: $I_A = 5.5597 \times 10^{-39}$, $I_B = 34.2573 \times 10^{-39}$ and $I_C = 39.8170 \times 10^{-39}\ g \cdot cm^2$.

Bond Angles: Cl–Al–F = [120]°; Cl–Al–Cl = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [3.841449 \times 10^{-113}]\ g^3 \cdot cm^6$

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -189.0 \pm 1.5\ kcal \cdot mol^{-1}$ and $\Delta_a H° = 341.4 \pm 3\ kcal \cdot mol^{-1}$ based on $\Delta_f H°(298.15\ K) = 0.5 \pm 1\ kcal \cdot mol^{-1}$ for 2/3 $AlCl_3(g)$ + 1/3 $AlF_3(g)$ = $AlCl_2F(g)$. Krause and Douglas[1] obtained this result by an entrainment method which measured enhanced volatility of AlF_3 in the presence of $AlCl_3$. Corrections were made for all the possible dimers which can form in this system. The entrainment data establish that aluminum fluoride–chloride exchange reactions are almost thermoneutral.

Our adopted $\Delta_f H°$ is compared below with an approximate mass-spectrometric K_p for reaction of AlF_2 with $AlCl_2$.[2] The discrepancy in $\Delta_f H°(AlCl_2F)$ is −22 $kcal \cdot mol^{-1}$ if we use $\Delta_f H° = -180$ (AlF_2) and −71 ($AlCl_2$) derived from the mass-spectrometric data.[2, 3] The discrepancy almost disappears if we use $\Delta_f H° = -166$ (AlF_2) and −67 ($AlCl_2$) derived from average bond energies in AlF_3 and $AlCl_3$.[4] This favors the latter values of $\Delta_f H°$ for AlF_2 and $AlCl_2$,[4] although the discrepancy might arise from the observed ion intensity of $AlCl_2F^+$. The signal from $AlCl_2F^+$ was very weak at 40 eV;[5] this high ionizing energy might bias K_p and cause considerable fragmentation. We can eliminate AlF_2 and $AlCl_2$ by taking the difference between the mass–spectrometric reactions for $AlClF_2$[4] and $AlCl_2F$. This yields [$\Delta_f H°(AlClF_2)$–$\Delta_f H°(AlCl_2F)$] = −47 $kcal \cdot mol^{-1}$ which agrees with −49.8 $kcal \cdot mol^{-1}$ from entrainment data.[1] Thus, we tentatively ascribe the discrepancy to AlF_2[4] and $AlCl_2$.

					or	−211[b]

[a] Assuming $\Delta_f H°(298.15\ K) = -166$ (AlF_2) and −67 ($AlCl_2$) $kcal \cdot mol^{-1}$.
[b] Assuming $\Delta_f H°(298.15\ K) = -180$ (AlF_2) and −71 ($AlCl_2$) $kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

We adopt a C_{2v} structure with bond angles and bond distances assumed equal to those in AlF_3 and $AlCl_3$.[4] We assume a singlet electronic ground state and neglect excited states. Vibrational frequencies are estimated by comparison of AlF_3 and $AlCl_3$with the series BF_3, $BClF_2$, BCl_2F and BCl_3.[6, 7] The principal moments of inertia are: $I_A = 18.3596 \times 10^{-39}$, $I_B = 37.4744 \times 10^{-39}$ and $I_C = 55.8339 \times 10^{-39}\ g \cdot cm^2$.

PREVIOUS: June 1976 (1 atm) CURRENT: June 1976 (1 bar)

$S°(298.15\ K) = 109.29 \pm 0.42\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 465.7 \pm 0.2\ K$

$\Delta_f H°(0\ K) = -704.30 \pm 0.84\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -705.63 \pm 0.84\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 35.35 \pm 0.84\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The adopted enthalpy of formation, $\Delta_f H°(AlCl_3, cr, 298.15\ K) = -168.65 \pm 0.20\ kcal \cdot mol^{-1}$ ($-705.632 \pm 0.84\ kJ \cdot mol^{-1}$) is a weighted average of the values of Gross and Hayman[1] and of Coughlin.[3] NBS[4] recommended a value of $-704.2\ kJ \cdot mol^{-1}$ based on data available prior to 1968.

Gross and Hayman[1] measured the enthalpy of direct combination of "spectrographically pure" aluminum and carefully purified chlorine and derived $\Delta_f H°(298.15\ K) = -168.80 \pm 0.16\ kcal \cdot mol^{-1}$. Siemonsen[2] also reported the enthalpy of direct combination and is in agreement at $-167.5\ kcal \cdot mol^{-1}$ within his relatively large uncertainty interval of $\pm 1.1\ kcal \cdot mol^{-1}$. Coughlin[3] determined the enthalpy of solution of 99.99+% pure Al in 4.360 m HCl and also the enthalpy of solution of anhydrous $AlCl_3$ in the same solvent. Enthalpies of mixing were measured to close a thermochemical cycle at 303.15 K (adjusted to 1981 relative atomic masses).

Source	Reaction	$\Delta_r H°(303.15\ K)$, $cal \cdot mol^{-1}$
1	$Al(cr) + 3H^+(sln) = Al^{+++}(sln) + 3/2\ H_2(g)$	-127057 ± 120
2	$3(HCl \cdot 12.731\ H_2O)(l) = 3H^+(sln) + 3\ Cl^-(sln) + 38.193\ H_2O(sln)$	0 ± 10
3	$AlCl_3(cr) = Al^{+++}(sln) + 3\ Cl^-(sln)$	-72504 ± 50
4	$38.193\ H_2O(l) = 38.193\ H_2O(sln)$	-3050 ± 20
5	$Al(cr) + 3\ (HCl \cdot 12.731\ H_2O)(l) = AlCl_3(cr) + 38.193\ H_2O(l) + 3/2\ H_2(g)$	-51503 ± 140

With auxiliary data from JANAF[12] and CODATA,[5] the enthalpy of reaction (5) at 298.15 K is $-51910 \pm 140\ cal \cdot mol^{-1}$ $AlCl_3$. Interpolation of data for $\Delta_f H°(HCl, aq, 298.15\ K)$[4] yields $\Delta_f H°(AlCl_3, cr, 298.15\ K) = -168.32\ kcal \cdot mol^{-1}$. The overall uncertainty is estimated as 300 $cal \cdot mol^{-1}$. Semenenko *et al.*[6] also determined the enthalpy of solution of Al in (HCl, 11.13 H_2O) and of $AlCl_3$in (HCl, 11.26 H_2O). Their results yield a more negative value, $\Delta_f H°(AlCl_3, cr, 298.15\ K) = -170.1 \pm 0.4\ kcal \cdot mol^{-1}$. This discrepancy is due both to differences in the solution enthalpies measured for Al and $AlCl_3$. When adjusted to the conditions of Coughlin's experiments, Semenenko's enthalpy of reaction (1) is calculated to be $-128.20\ kcal \cdot mol^{-1}$ which deviates more significantly than the values calculated for other authors.[7] Semenenko's enthalpy of solution of $AlCl_3$, recalculated to solution in pure water at 20°C is $-77.46\ kcal \cdot mol^{-1}$, a more positive value than those found for other investigators.[7] The enthalpy of solution of $AlCl_3$ measured by Krivtsov *et al.*[8] and recalculated to these same conditions is $-78.66\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

Justice[9] reported low temperature heat capacity data (13 to 310 K) and presented smoothed thermodynamic functions, including $S°(298.15\ K) = 109.29\ J \cdot K^{-1} \cdot mol^{-1}$ of which $0.360\ J \cdot K^{-1} \cdot mol^{-1}$ is extrapolation below 13 K. Enthalpies relative to 273.15 K were measured by Fischer[10] from 298.15 K to 504 K and enthalpies relative to 298.15 K were measured by McDonald[11] from 310 K to 493 K. The enthalpy data for the crystal can be fit within about 2% by integration of $C_p°(cr) = 64.94 + 0.088\ T$ in $J \cdot K^{-1} \cdot mol^{-1}$, which is an extrapolation of $C_p°$ data reported by Justice.[9]

Fusion Data

Refer to the liquid table for details.

Sublimation Data

The enthalpy of sublimation is calculated from the enthalpies of formation of the dimer and the crystal for the sublimation process, $2\ AlCl_3(cr) = Al_2Cl_6(g)$, $\Delta_{sub} H°(298.15\ K) = 115.52 \pm 2.3\ kJ \cdot mol^{-1}$. Also refer to the Al_2Cl_6(g) table for additional comments.

PREVIOUS: June 1970 CURRENT: September 1979

$S°(298.15\ K) = [172.908]\ J·K^{-1}·mol^{-1}$ $\Delta_f H°(298.15\ K) = [-674.805]\ kJ·mol^{-1}$

$T_{fus} = 465.7 \pm 0.2\ K$ $\Delta_{fus}H° = 35.35 \pm 0.84\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(AlCl_3, l, 298.15\ K)$ is calculated from $\Delta_f H°(AlCl_3, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus}H°$, and the difference in enthalpy, $H°(465.7\ K) - H°(298.15\ K)$, between the crystal and the liquid.

Heat Capacity and Entropy

Fischer[1] and McDonald[2] measured enthalpy data for the crystal and liquid. In each case, the liquid data extended over a short range of temperature, 473–504 K and 475–493 K, respectively. Their data can be represented within 2% by the heat capacity equation derived for the crystal [see $AlCl_3$(cr) table], a heat of fusion of 35.35 $kJ·mol^{-1}$, and a liquid heat capacity of 125.5 $J·K^{-1}·mol^{-1}$. Fischer's data are high, while McDonald's points lie below the selected values.

$S°(298.15\ K)$ is calculated in a manner similiar to that used for the enthalpy of formation.

Fusion Data

Kendall *et al.*[3] observed $AlCl_3$ to melt "sharply" at 463.4 K. Foster[4] noted that $AlCl_3$ began melting and melted completely in the range 465.7 ± 0.2 K. Johnson *et al.*[5], Nisel'son *et al.*,[6] and Ostrikova *et al.*[7] reported melting temperatures of 465.9 ± 0.3 K, 467.2 K, and 466 K, respectively. Smits and Meyering,[8] Treadwell and Terebesi[9] and Viola *et al.*[10] derived triple point temperatures of 465.8 K, 466.5 K, and 466.86 K, respectively, from intersection of vapor pressure curves for crystal and liquid. The value of Foster, T_{fus} = 465.7 ± 0.2 K, is adopted as most accurate. The vapor pressure (monomer and dimer contributions) at the triple point is 2.3 atm. $\Delta_{fus}H°$ is based on enthalpies measured by Fischer[1] and McDonald.[2]

Enthalpy of Formation

The enthalpy of formation is calculated from the value adopted for Al_2Cl_6(g) and the heat of dissociation of $Al_2Cl_6 \rightarrow 2AlCl_3$ derived from equilibrium *PVT* data on aluminum chloride vapor as listed below.

The four investigations are in reasonable agreement. Giving consideration also to equilibrium data on the reaction of $AlCl_3$(g) and Al(l) to form AlCl(g) [see AlCl(g) table], there is selected as a best value Δ_fH°(298.15 K) = 30.25 kcal·mol^{-1} Al_2Cl_6, which yields Δ_fH°($AlCl_3$, g, 298.15 K) = −139.72 kcal·mol^{-1} (−584.59 ± 2.9 kJ·mol^{-1}). NBS[15] recommended a value of −139.4 kcal·mol^{-1} (−583.250 kJ·mol^{-1}) for the enthalpy of formation of $AlCl_3$(g) based on data available prior to 1968.

[a]Twenty–three points reported, points at 938, 881, 944, 734, 805 and 605 K rejected by statistical test.
[b]Twenty–six points reported, points at 627.9, 643.1, 671.3, 638.4, 671.6, 722.5 and 686.9 K rejected by statistical test.
[c]Individual points not reported, an equation for the equilibrium constant was used to calculate two points at the extremes of temperature.

Heat Capacity and Entropy

The structure of monomeric $AlCl_3$ has been the subject of considerable debate due to conflicting assignments made on the basis of the electron diffraction data of Zasorin and Rambidi[5] and the matrix–isolation IR study by Lesiecki and Shirk.[6] Electron diffraction of the vapor at 800 K yielded an Al–Cl bond length of 2.06 ± 0.01 Å and a Cl–Al–Cl angle of 118 ± 1.5°, which allowing for the possibility of "shrinkage" was taken to indicate a planar equilibrium D_{3h} geometry. The argon matrix spectra obtained by Lesiecki and Shirk[6] showed four infrared–active fundamentals including the symmetric stretch, implying a pyramidal C_{3v} structure; their normal coordinate analysis suggested a Cl–Al–Cl angle near 112°. Hargittai and Hargittai[7] argued, however, that the electron diffraction results for $AlCl_3$ are not compatible with a pyramidal model having an inversion frequency of 183 cm^{-1} and a barrier height equal to 2–3 vibrational quanta. Beattie *et al.*[8] were unable to reproduce the IR frequencies observed by Lesiecki and Shirk[6] in their own matrix isolation studies and it was later concluded that the earlier work by Lesiecki and Shirk was based on incorrect band assignments.[9] The D_{3h} structure is supported by the original electron diffraction work as well as theoretical calculations[10,11] and correlations[9] of the frequencies of $AlCl_3$, $AlCl_2Br$, $AlClBr_2$and $AlBr_3$.

For aluminum chloride vapor at high temperatures (monomer predominant), Klemperer[12] observed the band at 610 cm^{-1} in the IR spectrum and Beattie and Horder[13] reported Raman bands at 371 cm^{-1} and 146 cm^{-1}. The remaining fundamental is that reported by Lesiecki and Shirk;[6,9] a second experimental observation of ν_2 = 174 cm^{-1} was reported by Perov *et al.*[14] in a xenon matrix along with ν_1 = 350 cm^{-1}, ν_4 = 142 cm^{-1}. The principal moments of inertia are $I_A = I_B$ = 37.4744 × 10^{-39}, and I_C = 74.9488 × 10^{-39} g·cm^2.

$S°(298.15\ K) = [196.6 \pm 8]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 529\ K$

$\Delta_f H°(0\ K) =$ Unknown
$\Delta_f H°(298.15\ K) = -1196.6 \pm 10\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° =$ Unknown

Enthalpy of Formation

The enthalpy of reaction of aluminum chloride and potassium chloride was measured by Baud.[1] From $\Delta_r H° = -26.38\ kcal \cdot mol^{-1}$ for the reaction: $Al_2Cl_6(cr) + 2\ KCl(cr) = 2\ KAlCl_4(cr)$, the value of $\Delta_f H°(KAlCl_4, cr, 298.15\ K)$ is calculated to be $-286\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

Heat capacities are estimated by comparison with those for $KMgCl_3(cr)$ reported by Kelley.[5] $S°(298.15\ K) = 47 \pm 2\ cal \cdot K^{-1} \cdot mol^{-1}$ is estimated according to the methods suggested by Kubaschewski and Evans[2] and Kelley.[3]

$T_{fus} = 424\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -1142.2 \pm 4\ kJ·mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

$\Delta_f H°(NaAlCl_4, cr, 298.15\ K)$ is calculated from $\Delta_r H° = -11.9\ kcal·mol^{-1}$ for the reaction $Al_2Cl_6(cr) + 2\ NaCl(cr) = 2\ NaAlCl_4(cr)$, as measured by Baud.[1]

Heat Capacity and Entropy

Heat capacities are estimated by comparison with those of $KAlCl_4(cr)$. $S°(298.15\ K) = 45 \pm 2\ cal·K^{-1}·mol^{-1}$ is estimated according to the methods suggested by Kubaschewski and Evans[2] and Kelley.[3]

Fusion Data

T_{fus} was reported by Fischer and Simon.[4]

$S°(298.15\ K) = [376.6 \pm 8]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = [800 \pm 20]\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -2092 \pm 4\ kJ \cdot mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

$\Delta_f H°(K_3AlCl_6, cr, 298.15\ K)$ is recalculated from the same quantity given by Rossini *et al.*[1] The latter value was derived from the enthalpy change for the reaction $Al_2Cl_6(cr) + 6\ KCl(cr) = 2\ K_3AlCl_6(cr)$, as measured by Baud.[2]

Heat Capacity and Entropy

Heat capacities are estimated by comparison with the corresponding values of the sum of the constituent halides for K_3AlCl_6(cr). In a similar manner, $S°(298.15\ K)$ is estimated to be $90 \pm 2\ cal \cdot K^{-1} \cdot mol^{-1}$.

Fusion Data

T_{fus} is estimated by comparison with that for K_3AlF_6(cr).

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -63.5 \pm 0.8$ kcal·mol^{-1} (-265.684 ± 3.35 kJ·mol^{-1}) and $D_0° = 160.0 \pm 1.5$ kcal·mol^{-1} (669.440 ± 6.3 kJ·mol^{-1}) based on our analysis of numerous equilibrium data.[1-12] We only tabulate our analysis of three studies; the other analyses are essentially those which were reported earlier.[22] However, the previously calculated $D_0°$ values will differ due to a more current heat of formation for Al(g). Greatest weight is given to torsion effusion[2] and transport[5,12] data for the Al–AlF_3 system. Hildenbrand *et al.*[2] found that orifice area affected the torsion–effusion pressures of AlF from reaction A. They derived equilibrium pressures from a semi–empirical correlation of data for the four cells listed below. Mass–spectrometric studies[9] of the Al–AlF system near 950 K indicated that the vapor consists of AlF with a small amount of AlF. The adopted $D_0° = 669.440 \pm 6.3$ kJ·mol^{-1} is consistent with $D_0° > 665.6$ kJ·mol^{-1} derived from the highest observed level in $A^1\Pi$.[14] The potential energy curve of this excited state may have a maximum.[14,15]

[b]P = equilibrium pressure and P_t = torsion pressure. [c]One point rejected.

Heat Capacity and Entropy

Electronic levels and molecular constants are based on the detailed analysis of electronic spectra published by Barrow, Kapp and Malmberg[16] and a follow-up to this investigation published by Kapp and coworkers.[20] Constants for the ground state are confirmed by microwave spectra.[11,17,18] The triplet–singlet separation, a^3–$X^1\Sigma^+$, calculated by Barrow *et al.*[16] is in excellent agreement with the results from the low resolution chemiluminiscence work of Rosenwaks *et al.*[21] We omit electronic states between 60000 and 68000 cm^{-1} including nine observed levels and one predicted level;[16] these would have negligible effects on the thermodynamic functions. The analysis of Barrow *et al.*[16] is supported by theoretical calculations.[20,21]

Enthalpy of Formation

We adopt $\Delta_f H°$ = 164 ± 6 $kcal·mol^{-1}$ based on IP(AlF) = 9.86 ± 0.25 eV (227.5 ± 6 $kcal·mol^{-1}$). Barrow, Kopp and Malmberg[1] used the observed data for BF to predict that, to a good approximation, IP(AlF) = $T°$(AlF, 3d) + IP(Al, 3d). This gave IP(AlF) = 79335 cm^{-1} (9.84 eV) which the authors[1] rounded to 80000 cm^{-1} (9.92 eV). We adopt an intermediate value corresponding to $\Delta_f H°$ = 164 $kcal·mol^{-1}$. This yields $D_0°$ = 70 ± 6 $kcal·mol^{-1}$ for $AlF^+(g) \rightarrow Al^+(g) + F(g)$.

IP(AlF) = 9.86 ± 0.25 eV is consistent with electron impact data which gave the following values for the appearance potential of AlF + from AlF: 8.9 ± 0.6,[2] 9.0 ± 1,[3] 9.2,[4] 9.5 ± 0.5,[5] 9 to 10,[6] 9.7 ± 0.3,[7] 9.7 ± 0.5,[8] 9.9 ± 0.3,[8] and 10.1 ± 0.3 eV.[8]

Heat Capacity and Entropy

We assume the ground-state configuration to be the same as observed for BF^+ [9] and the isoelectronic molecules AlO and AlF.[10] Theoretical calculations for $AlCl^+$ [11] predict the same ground state; they also suggest that the $^2\Pi$ excited state is either repulsive or has a shallow potential minimum at a much longer bond length. We assume the $^2\Pi$ state in AlF^+ to be nonrepulsive and estimate excited state levels equal to those in AlO.[10] Comparison with $AlCl^+$ suggests that $^2\Pi$ should be in the range 5000–15000 cm^{-1}. Our thermodynamic functions would be upper-limit values if the $^2\Pi$ state were repulsive.

Bonding in Group III monohalides and their ions was characterized by Berkowitz and Dehmer[11] from photoelectron spectra and theoretical calculations. They concluded that ionization removes an electron from an antibonding orbital centered mainly on the metal. This shortens the bond length and enhances the ionic nature of the bond. A decrease in bond length is observed for BF^+ [9] and predicted by theroretical calculations for $AlCl^+$.[11,10] By analogy with BF^+ and BF,[9] we expect AlF^+ to have vibrational and rotational constants similar to those of the Rydberg excited states of AlF.[1,10] Our adopted constants are approximate avarages from the Rydberg states. The adopted bond length is 0.05 Å shorter than in ground state AlF; a similar difference is observed for BF^+.

Rotational Constant: B_o = [0.184214] cm^{-1}

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -139 \pm 4$ kcal·mol^{-1} and $\Delta_{at}H° = 293.2 \pm 4$ kcal·mol^{-1}, derived from effusion data for reaction A.[1] This reaction is analyzed along with limited equilibrium data for three other reactions. The latter are in satisfactory agreement with reaction A. Dissociation energies calculated from our adopted values[5] are 13.9 kcal·mol^{-1} larger than those of the corresponding diatomic molecules; i.e., $\Delta_{at}H°$ (FAl–O) = 133.9 ± 4, $\Delta_{at}H°$(OAl–F) = 173.2 ± 4, or $\Delta_r H° = 13.9 \pm 5$ kcal·mol^{-1} for the reaction OAlF(g) + Al(g) = AlF(g) + AlO(g). These values suggest that O=Al–F has enhanced stability, consistent with the observation of this reaction[4] by mass-spectrometric sampling of flames containing aluminum species. We assign $\Delta_f H°$ the alternative uncertainty of ±7 kcal·mol^{-1} in case OAlF is nonlinear. Farber and Srivastava[4] emphasized that $\Delta_f H°$ is much too negative to be compatible with the alternative arrangement Al–O–F.

Source	Method	Reaction[a]	T/K	Data Points	δS cal·$K^{-1}·mol^{-1}$	$\Delta_r H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}

	Flame mass spec.	D	2250	1	—	—	−11.7	−133.0 ± 6

[a] Reactions:
A: 1/3 $AlF_3(g)$ + 1/3 $Al_2O_3(\alpha)$ = OAlF(g)
B: AlF(g) + $Al_2O(g)$ = OAlF(g) + 2 Al(g)
C: AlF(g) + AlO(g) = OAlF(g) + Al(g)
D: AlF(g) + $H_2O(g)$ = OAlF(g) + $H_2(g)$

[b] *T converted to IPTS–68 assuming published values to be IPTS–48.*

[c] Analysis based on relative ion intensities corrected [3] as follows: I(OAlF) = 66 at 1773 K and I(AlF) = 120 at 1923 K. Values of K_p were not measured, thus precluding third law analysis.

Heat Capacity and Entropy

Snelson[6] observed infrared spectra of OAlF, OBF, OBCl and OBBr isolated in inert gas matrices. He proposed linear structures for OBCl and OBBr based on agreement of observed and calculated shifts in isotopic frequencies. Isotopic shifts for OBF were consistent with linearity but were less conclusive. Lacking isotopic data, Snelson[6] assumed OAlF to be linear.

For triatomics having 16 valence electrons (either BAB or BAC types), a linear ground state is predicted by Walsh's correlation[7] and related semiempirical calculations.[8] These correlations derive mainly from covalent triatomics in which the central atom is carbon or some less electropositive element. Ionic triatomics can behave differently, e.g., the alkaine earth difluorides change from linear (BeF_2)[5] to bent configurations (CaF_2, SrF_2 and BaF_2).[9] OAlF is isoelectronic with and intermediate between MgF_2 and SiO_2. Electric deflection data indicated SiO_2 to be linear.[10] Data for MgF_2[5] are contradictory, indicating either a linear or slightly bent (~158°) structure. This comparison with SiO_2 *and MgF_2 favors linearity of OAlF but does not rule out a slightly bent structure.*

We adopt the linear structure O=Al–F with an O–Al distance slightly shorter than in AlO[5] and an Al–F distance equal to that in AlF_3.[5] We assume the ground-state configuration to be $^1\Sigma^+$ and neglect excited states which should be relatively unimportant.[8] Vibrational frequencies are those assigned by Snelson[6] from a comparison of derived force constants for OAlF and OBX molecules. Values of ν_2 and ν_3 from IR spectra in an argon matrix. Snelson[6] used a stretching force constant transferred from AlF_3 in order to estimate ν_1 = 675 cm^{-1}. Although a weak absorption was observed at 687 cm^{-1}, this band was not assigned[6] to ν_1 because it was not conclusively associated with ν_2 and ν_3.

We estimate the uncertainty to be ~1 cal·K^{-1}·mol in the entropy and Gibbs–energy function of linear OAlF. If OAlF were nonlinear with an angle of 160°, $S°$ would change by +3.8 (298 K) and +2.1 (2000 K) cal·K^{-1}·mol, while the Gibbs–energy function would change by +2.9 cal·K^{-1}·mol at 2000 K.

Point Group: $[C_{2v}]$ $\sigma = 2$

Bond Distance: Al–F = [1.65] Å

Bond Angle: F–Al–F = [120]°

Product of the Moments of Inertia: $I_A I_B I_C = [3.369562 \times 10^{-115}]\ g^3 \cdot cm^6$

Enthalpy of Formation

We tentatively adopt $\Delta_f H°(298.15\ K) = -166 \pm 10\ kcal \cdot mol^{-1}$ which corresponds to an average bond energy, $\Delta_{at}H°/2 = 140\ kcal \cdot mol^{-1}$, similar to that in AlF_3(g).[1] $\Delta_f H°$ is a compromise between discrepant results (−0 and −151 $kcal \cdot mol^{-1}$) from two mass–spectrometric equilibria analyzed below. In our opinion there is possible cause to suspect K_p for either reaction. The large entropy discrepancy (δS) for reaction B suggests a temperature–dependent bias in the mass–spectrometric K_p.[5] If both AlF_2 and AlF_3 were determined from the intensity of AlF_2^+ at different ionizing energies, then we expect $\Delta_f H°$[5] to be a positive limit. Reaction A was studied twice by molecular flow effusion of AlF_3(g) over the system Al(l)–Al_2O_3(cr). The earlier study[3,4] yields $\Delta_f H°(298.15\ K) = -188$ or $-179\ kcal \cdot mol^{-1}$, depending on the ionizing energy. Unfortunately, the ionizing energy in the first case is ambiguous. We conclude that $\Delta_f H°$ is quite dependent on ionizing energy. In addition, K_p and $\Delta_f H°$ may be affected by bias in the ionizing energy scale or related problems. These are discussed in more detail on tables for AlF_2^+, $AlCl_2^+$ and $AlCl_2$.[1] We believe that $\Delta_f H°$ [3,4] may be a negative limit.

The later study[2] of reaction A yields $\Delta_f H° = -180\ kcal \cdot mol^{-1}$. Internal evidence[2] gives us no reason to suspect this value. The possibility of negative bias is suggested, however, by inference from average bond energies (see $AlCl_2$),[1] and by using $\Delta_f H° = -180$ to derive $\Delta_f H°$ of other species in related mass–spectrometric studies. Effects of alternative values of $\Delta_f H°(AlF_2)$ are discussed on the tables for Al_2^-, AlF_4^-, AlF_2O, AlClF, $AlClF_2$, and $AlCl_2F$.[1] Only for $AlClF_2$ and $AlCl_2F$ do we have reliable, independent values of $\Delta_f H°$. These are consistent with $\Delta_f H°(AlF_2) = -166$ instead of −180. Although an alternative explanation is conceivable (see $AlClF_2$),[1] we choose $\Delta_f H°(AlF_2) = -166\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The electronic ground state is that predicted for BF_2 by theoretical calculations;[6] it is consistent with semiempirical calculations[7] for BF_2, AlF_2, BCl_2 and $AlCl_2$. We estimate excited states of BF_2 at −30000 ($^2B_1$) and −40000 ($^2B_2$) by assuming that approximate theoretical calculations[6] have a bias similar to analogous calculations[8] of NO_2.[9] Dissociative electron–attachment data[10] yield −43000 cm^{-1} for $BF_2(^2B_2)$ confirming the estimation method. We use $BF_2(^2B_1)$ to estimate a crude correlation–energy correction for $AlF_2(^2B_1)$.[7] Dissociative electron–attachment data[11] for $AlF_2(^2B_2)$ are approximate; they yield −20000 ± 10000 ($\Delta_f H° = -166$) or −25000 ± 10000 cm^{-1} ($\Delta_f H° = -180$).

Vibrational frequencies are calculated from the estimated force constants $f_r = 4.25$ and $f_\alpha/r^2 = 0.25$ mdyn/Å. Frequencies and force constants are estimated from simultaneous consideration of AlF_2^+, AlF_2, AlF_2^-[1] and the analogous boron species. We assume that frequency changes are qualitatively similar to those of NO_2^+, NO_2 and NO_2^-. In going from AlF_2^+ to AlF_2, we expect a large decrease in ν_3, an increase in ν_2 and some increase in ν_1. By analogy with BF_2,[6] the odd electron in AlF should occupy an antibonding orbital which increases the bond length but decreases the bond angle and stretching force constant. We assume a bond length 0.05 Å longer than AlF_2^+[1] and a bond angle equal to that in BF_2.[6] The principal moments of inertia are: $I_A = 1.7832 \times 10^{-39}$, $I_B = 12.8835 \times 10^{-39}$ and $I_C = 14.6667 \times 10^{-39}\ g \cdot cm^2$.

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = 22 \pm 15$ $kcal·mol^{-1}$ and $IP(AlF_2) = 8.1 \pm 0.9$ eV. Electron–impact studies[1,2] gave 15.2 ± 0.3 eV for the appearance potential (AP) of AlF_2^+ from AlF_3. The analogous process for onset of BF_2^+ from BF_3 has been studied by both photoionization[3] and electron impact.[4] Comparison indicates that BF_2^+ from electron impact[4] carried an excess energy (E*) of −0.4 to −0.9 eV. We estimate the excess energy for AlF_2^+ as 1.0 ± 0.5 eV. Thus, we take $AP–E^* = \Delta_f H° = 14.2 \pm 0.6$ eV (327.5 ± 14 $kcal·mol^{-1}$) for the reaction $AlF_3(g) + e^-(g) = AlF_2^+(g) + F(g) + 2\ e^-(g)$. With JANAF auxiliary data[5] this yields $\Delta_f H°(AlF_2^+) = 21 \pm 15$, $\Delta_f H°(298.15\ K) = 22 \pm 15$ and $IP(AlF_2) = 187 \pm 20$ $kcal·mol^{-1}$ (8.1 ± 0.9 eV).

Electron–impact studies of AlF_2 gave approximate appearance potentials $AP(AlF_2^+) = 9 \pm 1$,[1] 10 ± 1[6] and 11 ± 1 eV.[7] We dismiss the last value[7] due to possible bias analogous to that of $AlCl_2^+(g)$.[5] Electron impact on AlF_2 should yield a vertical AP corresponding to a nonlinear (excited) configuration of AlF_2^+. Theoretical calculations for the linear $^2B_1$ state of BF_2[8] suggest an excitation energy of −1.1 eV at a bond angle of 120°. Extended Huckel calculations for AlF_2[9] suggest −1.4 eV at 130°. Thus, we combine $E^* = 1.2 \pm 0.5$ eV with the observed AP values[1,6] to get $IP(AlF_2) = 7.8 \pm 1.2$ and 8.8 ± 1.2 eV. These are consistent with the adopted value.

The extended Huckel calculation[9] gave $IP(AlF_2) = 7.8$ eV at a bond angle of 130°. This result should approximate the vertical IP which we expect at −9.3 eV.

Heat Capacity and Entropy

We assume the electronic ground state to be $^1\Sigma^+$ and neglect excited states. We expect the ground state to be linear by analogy with other triatomic species having sixteen valence electrons.[10] Although conflicting data[5] suggest that isoelectronic MgF_2 is either linear or slightly nonlinear, recent Raman data[11] favor a linear structure. We estimate the bond distance to be slightly shorter than that in AlF_3 and 0.05 Å shorter than that estimated for AlF_2.[5] We transfer the stretching force constant from AlF_3 and the ratio $f_r/f_\alpha = \sim 13$ $Å^{-2}$ from MgF_2. This ratio is a compromise between very different values of ν_2 observed for MgF_2 in the gas[5] and matrix[11] phases. Thus, we calculate vibrational frequencies for AlF_2^+ from the force constants $f_r = 4.9$, $f_{rr} = 0.2$ and $f_\alpha/r^2 = 0.14$ mdyn/Å. The resulting values have been rounded downward.

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -217 \pm 20\ kcal\cdot mol^{-1}$ which corresponds to an electron affinity of $EA(AlF_2) = 50 \pm 8\ kcal\cdot mol^{-1}$ (2.2 ± 0.4 eV) and a fluoride-ion affinity of $IA(AlF) = 92 \pm 20\ kcal\cdot mol^{-1}$. $\Delta_f H°$ is based on K_p data for the reaction $AlF_2(g) = F(g) + AlF_2^-(g)$ reported by Srivastava *et al.*[1] The authors measured K_p with a molecular-flow–effusion method using a mass spectrometer operating in both positive- and negative-ion modes. They give three points (1705–1900 K) obtained from study of the vapor species over the system AlF_3(cr)–KF(cr)–Al(l). Our analysis gives $[\Delta_r S°(2nd\ law) - \Delta_r S°(3rd\ law)] = -0.2 \pm 4.8\ cal\cdot K^{-1}\cdot mol^{-1}$ and $\Delta_f H°(298.15\ K) = 28.4 \pm 8.8$(2nd law) or 28.8 ± 1(3rd law) $kcal\cdot mol^{-1}$. Reducing the 3rd law $\Delta_f H°$ to absolute zero and combining with $EA(F) = 78.38\ kcal\cdot mol^{-1}$,[2] we derive $EA(AlF_2) = 49.7 \pm 8\ kcal\cdot mol^{-1}$. The uncertainty of ±8 $kcal\cdot mol^{-1}$ is our estimate of a reasonable bound for error in $\Delta_f H°$.

Depending on the value used for $\Delta_f H°(AlF_2)$, the above reaction yields $\Delta_f H°(AlF_2^-, g, 298.15\ K) = -231$,[3,2] -217[2] or -202[4,2] $kcal\cdot mol^{-1}$. In contrast, we derive $\Delta_f H°(AlF_2^-, g, 298.15\ K) = -181 \pm 25\ kcal\cdot mol^{-1}$, independent of $\Delta_f H°(AlF_2)$, from $\Delta_r H°(0\ K)$ AP–E* = 127 kcal[5] for the reaction $AlF_3(g) + e^-(g) = AlF_2^-(g) + F(g)$. Depending on $\Delta_f H°(AlF_2)$, this yields $EA(AlF_2) = 0 \pm 25$,[3,2] 14 ± 25[2] or 29 ± 25[4,2] $kcal\cdot mol^{-1}$. Petty *et al.*[5] measured the appearance potential (AP) and excess translational energy of AlF_2^- in the dissociative electron–attachment reaction. E*, the excess vibrational–translational energy of the products at threshold, was estimated[5] from the measured translational energy via an approximate empirical correlation. We estimate ±25 $kcal\cdot mol^{-1}$ as an approximate bound for error in E*.[6] The resulting $\Delta_f H°(AlF_2^-) = -181 \pm 25\ kcal^{-1}\cdot mol^{-1}$ is inconsistent with the two most likely values (−231 and −217) derived from AlF_2. Bias might exist in either experiment.[5,2] It is conceivable that AlF_2^- is formed[5] in an excited electronic state. Thus far, electronic excitation has been observed[7] in only one negative molecular ion, AsF_4^-. If it occurs for AlF_2^-, then $\Delta_f H° = -181 \pm 25$ refers to an excited electronic state. The electronic energy of this state would be $-13000 \pm 9000\ cm^{-1}$, based on the two most likely values of $\Delta_f H°(AlF_2^-)$. Such values are not unreasonable, so we cannot rule out electronic excitation.[5] We conclude that additional data are needed to confirm $\Delta_f H°(AlF_2^-)$.

Heat Capacity and Entropy

Electronic levels and quantum weights are assumed equal to those of isoelectronic SiF_2;[2,8] however, see the above comment on excited levels. Vibrational frequencies are calculated from the estimated force constants $f_r = 3.7$, $f_{rr} = 0.1$ and $f_\alpha/r^2 = 0.29$ mdyn/Å. Frequencies and force constants are estimated from simultaneous consideration of AlF_2^+, AlF_2, AlF_2^- and the analogous boron species. We assume that frequency changes are qualitatively similar in the two series AlF_2^+, AlF_2, AlF_2^- and NO_2^+, NO_2, NO_2^- [2] which have the same number of valence electrons. Furthermore, we expect isoelectronic SiF_2^{2-} to provide upper-limit frequencies for AlF_2^-. Thus, in going from AlF_2 to AlF_2^-, we assume little change in ν_1 and ν_2 but a significant decrease in ν_3.

By analogy with BF_2,[8,9] we expect that the odd electron in AlF_2 occupies a molecular orbital centered mainly on the metal opposite the two fluorines. This orbital should be antibonding[8] in the sense that addition of an electron increases the bond length but decreases the bond angle and stretching force constant. We assume that the bond length is 0.05 Å longer and the bond angle is 15° smaller than in AlF_2.[2] The principal moments of inertia are $I_A = 2.8061 \times 10^{-39}$, $I_B = 11.4773 \times 10^{-39}$and $I_C = 14.2834 \times 10^{-39}\ g\cdot cm^2$.

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -265 \pm 7$ kcal·mol^{-1} and $\Delta_{at} H° = 437 \pm 8$ kcal·mol^{-1} based on JANAF auxiliary data[1] combined with $\Delta_f H°(298.15\ K) = 15.5 \pm 5$ kcal·mol^{-1} for the reaction AlF(g) + AlFO(g) = Al(g) + AlF_2O(g). $\Delta_f H°$ is from our 3rd law analysis of K_p data reported by Uy *et al.*[2] They calculated K_p directly from ion intensities observed at 1453–1675 K in a mass-spectrometric study of vapor species over the system AlF_3(g)–Al(l)–Al_2O_3(cr). 2nd law analysis gives $\Delta_r H°(298.15\ K) = 20.8 \pm 0.8$ kcal·mol^{-1} and the difference $[\Delta_r S°(2nd\ law) - \Delta_r S°(3rd\ law)] = 3.4 \pm 0.5$ cal·K^{-1}·mol^{-1}. Uy *et al.*[2] assigned $\Delta_f H°$(2nd law) an overall uncertainty (including contributions from T) of ± 5 kcal·mol^{-1}.

The adopted $\Delta_{at} H° = 437$ kcal·mol^{-1} implies that AlF_2O is surprisingly stable. Average bond energies from AlF_3 (140 kcal·mol^{-1}) and AlO, AlO_2 and Al_2O (−120 kcal·mol^{-1}) yield an estimate of $\Delta_a H°(AlF_2O) = 400$ kcal·mol^{-1}. If we attribute all of the difference to the Al–O bond, then the AlF_2O data imply an Al–O bond energy of 157 kcal·mol^{-1}. This enhancement of 37 kcal·mol^{-1} contrasts with the near equality of Al–O bond energies in the oxides[1] and hydroxides.[8] An analogous treatment of AlFO(g)[1] yields an Al–O bond energy of 153 kcal·mol^{-1}, similar to that in AlF_2O. Existing data for BF_2O and BFO imply bond energies of −166 and −200 kcal·mol^{-1} compared with values of −130 (B–O) and −190 (B=O) from the oxides. There are obvious differences between the Al and B systems which we are unable to rationalize via existing knowledge of electronic structure. We feel that confirmation of the oxyfluoride data is desirable.

Heat Capacity and Entropy

Molecular parameters are all estimated by analogy with BF_2O and BF_2O^+. Two emission bands due to BF_2O or BF_2O^+ were analyzed by Mathews.[3] Vibrational analysis of the band with $\nu_\infty \approx 17171\ cm^{-1}$ gave the three symmetrical stretching modes of the lower state. Rotational analysis of the band with $\nu_o = 22391\ cm^{-1}$ gave structural parameters including the bond length B–O = 1.40 ± 0.05 Å. This value indicates a single bond which is longer than those of 1.36, 1.263 and 1.20 A observed for the various bond types in B_2O_3, BO_2 and BO. It is not known[3] whether the two emission bonds have a common lower state. Zahradnik and Carsky[4] used semiempirical CNDO calculations to predict the electronic transitions of BF_2O and BF_2O^+. They favored assignment of the 22391 cm^{-1} transition to BF_2O^+ and the other transition to either BF_2O^+ or BF_2O.

Due to the lengthened B–O bond and the theoretical results, we tentatively attribute both observed bands to BF_2O^+. We estimate the missing vibrational frequencies of BF_2O^+ and all those of BF_2O and BF_2O^- by comparison with HBF_2, BF_3 and $ClBF_2$. We assume that addition of an electron causes a large increase in ν_1 and ν_5 but a smaller increase in ν_2 and ν_6.

Vibrational frequencies of AlF_2O are estimated from those of BF_2O by comparison of AlF_3, AlFO, AlO and Al_2O[1] with the analogous boron species. Electronic levels are crude estimates based on calculations or data for the 24-valence-electron species BF_2O,[4] BF_3^+,[5,6] and NO_3.[5,7] Bond angles are assumed to be 120°. Bond distances are assumed equal to those of AlF_3 and Al_2O[1]. The principal moments of inertia are: $I_A = 12.0265 \times 10^{-39}$, $I_B = 12.5730 \times 10^{-39}$ and $I_C \approx 24.5995 \times 10^{-39}\ g \cdot cm^2$.

Ground State Quantum Weight: [1] σ = [2]
Point Group: [C_{2v}]
Bond Distances: Al–F = [1.63] Å; Al–O = [1.66] Å
Bond Angles: F–Al–F = [120]°; F–Al–O = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [3.468404 \times 10^{-114}]\ g^3 \cdot cm^6$

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -313 \pm 25$ kcal·mol^{-1} which corresponds to $EA(AlF_2O) = 46 \pm 25$ kcal·mol^{-1} (2.0 ± 1.1 eV) and the fluoride–ion affinity IA(AlFO) = 112 kcal·mol^{-1}. $\Delta_f H°$ is derived from Kp for reaction A (see below) observed by Faraber *et al.*[1] with a mass spectrometer operating in both positive– and negative–ion modes. Farber *et al.*[1] used a molecular–flow–effusion technique to study vapor species in the systems KF(g)–AlF_3(g)–Al_2O_3(cr), KF(g)–AlF_3(g)–Al_2O_3(cr), and KCl(g)–AlF_3(g)–Al_2O_3(cr). They considered the results to be limiting values; we presume this is due to very low intensities of AlF_2O^-.

The three reactions reported by Farber *et al.* are analyzed below using JANAF auxiliary data.[2] We give inequalities consistent with the authors' limiting values. Reactions B and C yield less stringent limits are are not used. Reaction A involves AlF_2^- which depends on our possibly biased value[2] of $\Delta_f H°(AlF_2)$. Use of the alternative $\Delta_f H°$ [2] based on mass spectrometry[1,3] reduces the discrepancy between reactions A and C form 35 to 21 kcal·mol^{-1}. This may mot be significant if B and C yield only limiting values. The alternative result from A would yield $EA(AlF_2O)$ = 61 and IA(AlFO) = 127 kcal·mol^{-1}.

Reaction	Data Points	T/K	$\Delta_r H°(298.15\ K)$ kcal·mol^{-1}	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}
A) $AlFO(g) + AlF_2^-(g) = AlF_2O^-(g) + AlF(g)$	1	1793	≥−21.1	≥−313.6[a] or ≥ − 327.8[a]
B) $AlF_2O(g) + F^-(g) = AlF_2O^-(g) + F(g)$	1	1753	>0.1	>−344.8
C) $AlF_2O(g) + Cl^-(g) = AlF_2O(g) + Cl(g)$	2	1653–1793	>0.8	>−349.1

[a]Assuming $\Delta_f H°(AlF_2^-, g, 298.15\ K)$ = −217 or −231.2 kcal·mol^{-1} depending on choice of $\Delta_f H°(AlF_2)$.[2]

Heat Capacity and Entropy

All molecular parameters are estimated via data for BF_2O^+ (or BF_2O) as discussed on the table for $AlF_2O(g)$.[2] We assume a C_{2v} structure with equal bond angles. Formation of the negative ion is assumed to decrease the Al–O bond distance by 0.06 Å but leave the Al–F distance unchanged. By analogy with AlF_3^2 we assume a singlet electronic ground state and neglect excited states. Formation of the negative ion is assumed to cause a significant increase in ν_1, ν_5, and ν_6. The principal moments of inertia are $I_A = 11.4723 \times 10^{-39}$, $I_B = 12.5732 \times 10^{-39}$, and $I_C = 24.0455 \times 10^{-39}$ g·cm^2.

$S°(298.15\ K) = 66.48 \pm 0.42\ J·K^{-1}·mol^{-1}$
$T_{trs} = 728 \pm 1\ K$
$T_{fus} = [2523 \pm 100]\ K$

$\Delta_f H°(0\ K) = -1504.3 \pm 1.3\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -1510.4 \pm 1.3\ kJ·mol^{-1}$
$\Delta_{trs} H° = 0.5632 \pm 0.042\ kJ·mol^{-1}$
$\Delta_{fus} H° = [98.3 \pm 12]\ kJ·mol^{-1}$

Enthalpy of Formation

The adopted value is that recommended by CODATA.[1] It is based on separate calorimetric studies of the combustion in fluorine of aluminum[2] and aluminum–Teflon mixtures.[3] More extensive auxiliary data[3] for Teflon bring the aluminum–Teflon study into exact agreement with the aluminum study.[2] Calorimetric data relating AlF_3 to PbF_2[2,4] tend to confirm this value, but PbF_2 is probably less certain than is AlF_3.

Values for the $\Delta_f H°(298.15\ K)$ derived indirectly from equilibrium studies[5] and emf of solid galvanic cells[6,7,8,9] are tabulated below. The original data are reanalyzed with the use of the most recent auxiliary data.[4]

Source	Method	Reaction	T/K	$\Delta_r H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	Drift cal·K^{-1}·mol^{-1}	$\Delta_f H°(298.15\ K)$* kcal·mol^{-1}

[6]	emf	B	873	—	−43.01	—	−360.0
[7]	emf	B	873	—	−42.73	—	−360.3
[8]	emf	B	720–860	−40.26 ± 0.01	−41.47 ± 0.2	−1.5 ± 0.01	−361.6
[9]	emf	B	748–903	−42.1 ± 0.01	−40.58 ± 0.2	−1.8 ± 0.02	−362.5

*Derived from the third law enthalpy of reaction and is per mole of AlF_3(cr).
A. 2/3 AlF_3(cr) + H_2O(g) = 1/3 Al_2O_3(α,cr) + 2 HF(g) B. AlF_3(cr) + 1.5 Mg(cr) = Al(cr) + 1.5 MgF_2(cr)

With the exception of the equilibrium study of Mashovets and Yudin,[5] the results are in reasonable agreement with the directly measured calorimetric value. It has been suggested[2] that interaction of the condensed phases (activities1) caused the equilibria to deviate from the standard-state reaction assumed above. An alternative may be that the reaction with water vapor produced Al_2O_3 in a metastable form; such forms require ignition temperatures greater than 1400 K for complete conversion to α- Al_2O_3.[10]

Heat Capacity and Entropy

$C_p°$ and $S°(298.15\ K)$ are taken from Douglas and Ditmars,[11] whose tables are based on heat capacity measurements from 54 to 298 K[12] and relative enthalpy measurements from 323 to 1173 K.[11] The enthalpy data confirm earlier data (401–1401 K) of O'Brien and Kelley[13] rather than the adjusted values proposed by Frank.[14] Douglas and Ditmars[11] gave a detailed comparison with other data. The entropy is derived from $C_p°$ using the extrapolation $S°(50\ K) = 2.22 \pm 0.25\ J·K^{-1}·mol^{-1}$.

Transition Data

T_{trs} and $\Delta_{trs} H°$ for this crystalline first order transition are from Douglas and Ditmars.[11] The values were obtained from extensive enthalpy data for the transition region assuming the presence of a very small amount of impurity in solid solution.

Sublimation Data

$T_{sub} = 1549$ K is the temperature at which the calculated total pressure (monomer plus dimer) reaches one atm; the mole fraction of dimer is calculated as 0.109 at T_{sub}. Sublimation temperatures of 1533 and 1566 K were obtained in two sublimation- pressure studies[15,16] at the Techische Hochschule, Breslau. The selected enthalpies of sublimation to AlF_3(g) and Al_2F_6(g) reproduce closely the entrainment data of Krause and Douglas.[17] Selection of these values of $\Delta_{sub} H°$ and comparisons with other vapor-pressure data are discussed on the gas-phase tables.

Fusion Data

Refer to the liquid table for details.

PREVIOUS: June 1970 CURRENT: September 1979

$S°(298.15\ K) = [95.379]\ J·K^{-1}·mol^{-1}$
$T_{fus} = [2523 \pm 100]\ K$

$\Delta_f H°(298.15\ K) = [-1422.760]\ kJ·mol^{-1}$
$\Delta_{fus}H° = 98.3 \pm 12\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(AlF_3, l, 298.15\ K)$ is calculated from $\Delta_f H°(AlF_3, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus}H°$, and the difference in enthalpy, $H°(2523\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

There are no heat capacity or enthalpy measurements covering the liquid region of AlF_3. The pure solid does not melt at ordinary pressures. This AlF_3(l) table, therefore, is a non-standard state table for P = −4400 atm. By analogy[1] with $AlCl_3$(l), $AlBr_3$(l), and AlI_3(l), we estimate $C_p°(l) = 30\ cal·K^{-1}·mol^{-1}$; Holm[2,3] also assumed the same value. We assume a glass transition at 1850 K, below which we adopt the heat capacity data of AlF_3(cr); the transition at 728 K for AlF_3(cr) is not included.

The entropy is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

The pure solid sublimes before melting at ordinary pressures. From studies on CaF_2–AlF_3 and NaCl–AlF_3 binary systems, Millet *et al.*[4] estimated a triple point temperature for AlF_3 of 2523 K at 30000 atm. Our adopted values lead to a pressure for $AlF_3(l) = AlF_3(g)$ of −2200 atm. The calculated dimer pressure at this temperature is also −2200 atm.

Holm,[3] attempted to relate his drop-calorimetric data on the melting of a Li_3AlF_6–AlF_3 system to the enthalpy of fusion of AlF_3. Based on the assumption that the enthalpy of mixing of Li_3AlF_6(l) with AlF_3(l) to form the eutectic mixture is small and positive, he obtained $\Delta_{fus}H° = 11.4\ kcal·mol^{-1}$ for AlF_3 at 1298 K. This result was challenged by Hong and Kleppa[4,5] who measured the enthalpy of mixing of AlF_3(cr) with a series of liquid alkali fluorides and derived $\Delta_{fus}H° = 26.5 \pm 2\ kcal·mol^{-1}$ at this temperature. These results suggest that Holm's assumed enthalpy of mixing is in error, both as to sign and magnitude. We adopt the $\Delta_{fus}H°$ value of Hong and Kleppa[5,6] but adjust the value to the adopted triple point of 2523 K (from 1298 K).

Ground State Quantum Weight: [1] $\sigma = 6$

Point Group: D_{3h}

Bond Distance: Al–F = 1.63 ± 0.01 Å

Bond Angle: F–Al–F = 120°

Product of the Moments of Inertia: $I_A I_B I_C = 3.975102 \times 10^{-114}\ g^3 \cdot cm^6$

Enthalpy of Formation

The enthalpy of formation is calculated from that of the crystal by use of $\Delta_{sub}H°(298.15\ K) = 71.965 \pm 0.5\ kcal \cdot mol^{-1}$. Sublimation studies by mass-spectrometric and entrainment techniques suggest the presence of a small amount of dimer in the saturated vapor. These studies are reviewed on the table for $Al_2F_6(g)$. The heats of sublimation for the monomer and dimer are selected by adopting the JANAF entropies for crystal, monomer and dimer, the mass spectrometric value of 2 $\Delta_{sub}H°$(monomer)–$\Delta_{sub}H°$(dimer) = −49 $kcal \cdot mol^{-1}$ at 1000 K, and the entrainment data of Krause and Douglas.[1] The resulting calculated pressures deviate by <0.5% from the entrainment data,[1] by <10% from the mass-spectrometric equation[3] and by <3% from the mass-effusion equation.[4]

Further comparisons with experimental data are given below. The adopted values favor the later[11] of two sublimation-point studies;[11, 12] both show considerable scatter and similar deviations from the calculated dP/dT. Torsion-effusion data suggest the possibility of more serious discrepancy. Although data of Witt and Barrow[9] are consistent with the JANAF pressures, Hildenbrand *et al.*[7, 8, 19] noted a trend toward increasing pressure with decreasing orifice area. The most recent study by Hildenbrand and Laughlin[19] yielded equilibrium pressures that are reasonably consistent with the adopted values, unlike the earlier study.[7] The 1981 communication[19] yielded a heat of sublimation value which is within 0.25 kcal·mol of our adopted value. In contrast, the JANAF predictions agree closely with mass-effusion data of Ko *et al.*,[4] who reported no significant effect from a twelvefold variation in orifice area.

Comparison of Calculated and Observed Total Pressures Over AlF_3(cr)

[a]Magnitude and sign of the difference, calculated minus observed, in dP/dT

[b]Absolute pressures of monomer were obtained by integration of the ion intensity during total sublimation.

Heat Capacity and Entropy

The molecular structure is that derived from electron-diffraction data by Akishin *et al.*[13] Observed vibrational frequencies are those reported by Buchler *et al.*[14] from infrared spectra of the vapor at 1000–1200 K. These frequencies are confirmed by infrared spectra of AlF_3 isolated in matricies of neon, argon and krypton.[15, 16] Drake and Rosenblatt[17] have estimated the Raman-active fundamentals based on a correlation of vibrational frequencies and internuclear distances for the Group IIIA trihalides. They estimated $\nu_1 = 685\ cm^{-1}$ which would decrease $S°(298.15\ K)$ by 0.05 $cal \cdot K^{-1} \cdot mol^{-1}$ from our adopted value. We adopt $\nu_1 = 650 \pm 50\ cm^{-1}$ as derived from three other methods: (a) calculation of the force constant k_1 from ν_3 and ν_4; (b) comparison of $k_1(XY_3)/k(XY)$ for X = B, Al and Y = F, Cl, and Br; and (c) extrapolation of $\nu_1(BY_3)/\nu_1(AY_3)$ to Y=F from Y=Cl, Br and *I*, using recent gas-phase Raman data[18] for AlY_3. The principal moments of inertia are: $I_A = I_B = 12.5730 \times 10^{-39}$ and $I_C = 25.1460 \times 10^{-39}\ g \cdot cm^2$.

Ground State Quantum Weight: [1] $\sigma = 12$
Point Group: T_d
Bond Distance: Al–F = 1.69 Å
Bond Angle: F–Al–F = 109.4712°
Product of the Moments of Inertia: $I_A I_B I_C = 1.387252 \times 10^{-113}\ g^3·cm^6$

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = -476 \pm 25\ kcal·mol^{-1}$ which corresponds to the fluoride-ion affinity $IA(AlF_3) = 125 \pm 25\ kcal·mol^{-1}$ for $AlF_4^-(g) = AlF_3(g) + F^-(g)$. $\Delta_f H°$ is a compromise based mainly on K_p data (7 points, 1130–1485 K) for the reaction $2\ AlF_2(g) + AlF_2^-(g) = 2\ AlF(g) + AlF_4^-(g)$. K_p data were measured by Srivastava *et al.*[1] with a mass spectrometer operating in both positive- and negative-ion modes. The authors used a molecular-flow-effusion technique to react vapors from AlF_3 and K_3AlF_6 or KF with Al(l). Analysis with JANAF auxiliary data[2] yields $\Delta_r H°(298.15\ K)$(3rd law) = −38.2 ± 2.7 and $\Delta_r H°(298.15\ K)$(2nd law) = −33.9 ± 6.3 $kcal·mol^{-1}$ with $[\Delta_r S°(2nd\ law) - \Delta_r S°(3rd\ law)] = -3.3 \pm 4.8\ cal·K^{-1}·mol^{-1}$. The 3rd law $\Delta_r H°$ yields $\Delta_f H°(AlF_4^-, g, 298.15\ K) = -460.4 \pm 14\ kcal·mol^{-1}$ or $-502.4 \pm 14\ kcal·mol^{-1}$, depending on the choice of $\Delta_f H°(AlF_2, g, 298.15\ K) = -166 \pm 10^2$ or $-180 \pm 5\ kcal·mol^{-1}$.[2,3]

The difference of 14 $kcal·mol^{-1}$ in $\Delta_f H°(AlF_2)$ causes a three-fold change (42 $kcal·mol^{-1}$) in $\Delta_f H°(AlF_4^-)$ and increases the fluoride-ion affinity $IA(AlF_3)$ from 109 ± 25 to 151 ± 15 $kcal·mol^{-1}$. The latter value seems rather large in comparison to related species:[2,1] ≤112 or ≤127(OAlF), 92 or 106 (AlF), ≤101 (BF_3), ≤92 (OBF) and 98 or 103 (BF).

By combining published data for $NaAlF_4$(g) with a coulomb-energy calculation, Holm[4] estimated $IA(AlF_3) = 131\ kcal·mol^{-1}$. This result has an unknown bias due to limitations of the calculational model and auxiliary data. Refined lattice energy calculations[5] yield halide-ion affinities IA = 87 ± 7 ($AlCl_3$) and ($AlBr_3$) $kcal·mol^{-1}$. $\Delta_f H°(BF_4^-) = -421\ kcal·mol^{-1}$ [6] derived from lattice energy yields $IA(BF_3) = 90$ compared to ≤101 $kcal·mol^{-1}$ from mass spectrometry. Comparison of stretching force constants[2,7,8] with average bond energies in AlX_3 and AlX_4^- suggests a slight, but not definitive, preference for $IA(AlF_3) = 109\ kcal·mol^{-1}$. As a compromise, we adopt $IA(AlF_3) = 125 \pm 25$ and $\Delta_f H°(AlF_4^-, g, 298.15\ K) = -476 \pm 25\ kcal·mol^{-1}$.

Heat Capacity and Entropy

Vibrational frequencies are from Raman spectra of AlF_4^- observed in molten salt mixtures of AlF_3 with NaF or KF.[8] Similar spectra were observed in mixtures of AlF_3 with LiF.[9] The spectra[8] are consistent with T_d symmetry except for some asymmetry in ν_3 which was attributed to influence of the metal ion. By analogy with SiF_4,[2] we assume a singlet electronic ground state and neglect excited states. The bond distance *is that derived from high-temperature electron diffraction*[10] *of* $NaAlF_4$*(g). Within experimental uncertainty, the* AlF_4 *grouping was found to* be tetrahedral.[2,10] The principal moments of inertia are $I_A = I_B = I_C = 24.0280 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: [1] σ = [2]

Point Group: [C_{2v}]

Bond Distances: Al–F_{br} = Al–F_{ter} = [1.69 ± 0.02] Å; Li–F_{br} = [1.68] Å

Bond Angles: F_{br}–Al–F_{br} = [110]°; F_{ter}–Al–F_{ter} = [109.47]°; F_{br}–Li–F_{br} = [110.98]°

Product of the Moments of Inertia: $I_A I_B I_C = 1.887733 \times 10^{-113}\ g^3 \cdot cm^6$

Enthalpy of Formation

Mass spectrometric studies[1,2,3] indicate that the vapor above the LiF–AlF_3 system is composed mainly of $LiAlF_4$, $(LiAlF_4)_2$, and Li_3AlF_5 with $LiAlF_4$ being the major component, 90% according to[1] or 77% according to.[3] For $(LiAlF_4)_2(g) = 2\ LiAlF_4(g)$, $\ln K_p = -48500/RT + 33.5/R$ at 946 K.[3] This is in agreement with the equilibrium constant for the dimer–monomer equilibrium of the sodium analog[4,5] which has been determined over a wider temperature range. As a first approximation, we ignore any gaseous species other than $LiAlF_4(g)$ and $(LiAlF_4)2$ (g) and adjust the total pressure measurements over the LiF–AlF_3 system to the partial pressure of $LiAlF_4(g)$ by assuming that $\ln K_p = -43900/RT + 28.50/R$ for the $(NaAlF_4)_2(g) = 2\ NaAlF_4(g)$ equilibrium[5] also represents the equilibrium of the lithium analog. Rao[6] has made a similar assumption.

$\Delta_f H°(298.15\ K)$ results from our 3rd law analysis of pressure measurements and equilibrium constants of the following:

[1] $Li_2F_2(g) + AlF_3(g) = LiF(g) + LiAlF_4(g)$

[2] $Li_3AlF_6(cr) = 2\ LiF(cr) + LiAlF_4(g)$

[3] $1/3\ Li_3AlF_6(cr) = 2/3\ AlF_3(cr) + LiAlF_4(g)$

[4] $LiAlF_4(g) = LiF(g) + AlF_3(g)$

[5] $LiF(l) + AlF_3(cr) = LiAlF_4(g)$

Dewing[10]	b	5	1293		59.155		−444.93

a. From third low heat of reaction plus auxiliary data.[11]

b. Dewing has determined activities of LiF and AlF_3 in LiF–AlF_3 melts and combined them with the vapor pressure measurement over the melts of Kuxmann and Tillessen[12] and Chin[13] to obtain an equilibrium constant for Reaction 5.

We give more weight to the results which lead to reasonable agreement in 2nd and 3rd law enthalpies of reaction and adopt $\Delta_f H°(LiAlF_4, g, 298.15\ K) = -443 \pm 3\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

We adopt the structural and vibrational frequency assignments given by Huglen *et al.*[14] While the C_{2v} structure has not been conclusively established, it is strongly supported by the interpolation of the infra-red spectroscopic studies,[14] by an electron diffraction study of $NaAlF_4$,[15] and by ab initio molecular orbital calculations.[16] The C_{2v} structure consists of an irregular AlF_4 tetrahedron combined with Li to form a planar ring, AlF_2Li, through coordination with two fluorines. Thus luminum forms two types of bonds, Al–F_{bridge} and Al–$F_{terminal}$, considered by Huglen *et al.*[14] to be the same length. A C_s structure and two C_{3v} structures have also been considered.

The AlF_4 tetrahedral angles and the Al–F_{br} and Al–F_{ter} bond distances are those from an electron diffraction study of $NaAlF_4$.[15] These are assumed to be the same for $LiAlF_4$. The Li–F_{br} bond length is estimated.[17] The F_{br}–Al–F_{br} and the F_{ter}–Al–F_{ter} angles are from the sodium analog;[17] the F_{br}–Li–F_{br} angle results from the adopted dimensions. The slightly different dimensions for the $LiAlF_4$ C_{2v} structures used by Cyvin [17] lead to a $S°(298.15\ K)$ value 0.12 cal·K·mol^{-1} less than the adopted values. The dimensions derived by Curtiss[16] in his ab initio study are quite different, but $S°(298.15\ K)$ is only 0.20 cal·K·mol^{-1} greater.

Nine vibrational frequencies were assigned by Huglen *et al.*[14] from infra-red matrix-isolation studies; the remaining three were calculated by force field analysis.[14]

The principal moments of inertia are $I_A = 24.1060 \times 10^{-39}$, $I_B = 27.9447 \times 10^{-39}$ and $I_C = 28.0231 \times 10^{-39}\ g \cdot cm^2$.

Bond Angles: F_{br}–Al–F_{br} = 110°; F_{ter}–Al–F_{ter} 109.47°; F_{br}–Na–F_{br} = 82°

Product of the Moments of Inertia: $I_A I_B I_C = 4.775246 \times 10^{-113}\ g^3 \cdot cm^6$

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ is based on our 3rd law analysis of pressure measurements of the NaF–AlF_3 system for the equilibria:

[1] $Na_3AlF_6(cr, \beta) = 2\ NaF(cr) + NaAlF_4(g)$ [3] $0.2\ Na_5Al_3F_{14}(cr) + 0.4\ AlF_3(cr) = NaAlF_4(g)$

[2] $Na_3AlF_6(l) = 02\ NaF(l) + NaAlF_4(g)$ [4] $0.5\ Na_5Al_3F_{14}(cr) = 0.5\ Na_3AlF_6(cr, \beta) + NaAlF4(g)$

The mass-spectrometric measurements of Sidorov *et al.*[1] showed that the most important species over solid phases in the NaF–AlF_3 system are $NaAlF_4(g)$ and the dimer $[NaAlF_4]_2(g)$. We ignore any other gaseous species in our data treatment. The enthalpy and entropy for the $[NaAlF_4]_2(g) = 2\ NaAlF_4(g)$ dissociation have been determined.

Investigator	T/K	$\Delta_{dso}H°$, $cal \cdot mol^{-1}$	$\Delta_{dso}S°$, $cal \cdot K^{-1} \cdot mol^{-1}$
Sidorov and Kolosov[2]	910	42600	27.14

Grjotheim, Kvande, and Motzfeldt[4]	1190–1420	43900	28.50

A plot of ln K_p vs 1/T shows Sidorov and Kolosov[2] and Grjotheim *et al.*[4] to be in excellent agreement. We use $\ln K_p = -43900/RT + 28.50/R$ to calculate the mole fraction $NaAlF_4$ monomer in the gas in order to correct the total pressure over the NaF–AlF_3 system to the partial pressure of monomer for the 3rd law analysis. The use of the total pressure rather than partial pressure leads to a heat of formation which is more negative by less than one $kcal \cdot mol^{-1}$.

*Partial pressures by the investigator.

The total vapor pressure over molten cryolite, reaction [2], measured by effusion by Grjotheim *et al.*,[4] corrected to monomer partial pressure, leads to $\Delta_f H°(NaAlF_4, g, 298.15\ K) = -447.70\ kcal \cdot mol^{-1}$. Unit activity of NaF in molten cryolite was used in this calculation so that $-447.70\ kcal \cdot mol^{-1}$ is a lower limit. There is no evident explanation for the more negative grouping of heats of formation from reactions [1] and [2] compared with the grouping from reactions [3] and [4].

In view of the difficulties and uncertainties in working with the NaF–AlF_3 system, we adopt $\Delta_f H°(NaAlF_4, g, 298.15\ K) = -440 \pm 3\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The adopted structure, C_{2v}, consists of an irregular AlF_4 tetrahedron combined with Na to form the planar ring, AlF_2Na, through coordination with two fluorines. The Al atom forms two types of bonds, Al–F_{bridge} and Al–$F_{terminal}$, which are of the same length.[8] Other structures have been considered, a C_s symmetry in which the ring is not planar and two C_{3v} structures where the Na is coordinated with one or three fluorines, but interpretation of the infra-red spectra supports the C_{2v} model.[9]

The bond distances and bond angles are from the electron diffraction study of Spiridonov and Erokin.[8] Seven vibrational frequencies were assigned from infrared matrx-isolation studies by Huglen *et al.*;[9] the remaining five were calculated by force field analysis.[9] The principal moments of inertia are $I_A = 24.1060 \times 10^{-39}$, $I_B = 44.4685 \times 10^{-39}$, and $I_C = 44.5470 \times 10^{-39}\ g \cdot cm^2$.

$S°(298.15\ K)$ = [284.5 ± 4] $J·K^{-1}·mol^{-1}$
T_{fus} = 1293 K

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K)$ = [−3326 ± 21] $kJ·mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

$\Delta_f H°(K_3AlF_6, cr, 298.15\ K)$ is calculated from $\Delta_r H° = -30.2\ kcal·mol^{-1}$ for the reaction, $AlF_3(cr) + 3\ KF(cr) = K_3AlF_6(cr)$, which was estimated by comparison with the values of $\Delta_r H°$ of the similar reactions for $Na_3AlF_6(cr)$, $Na_3AlCl_6(cr)$ and $K_3AlCl_6(cr)$.

Heat Capacity and Entropy

Heat capacities are estimated by the addition of a correction term $3(M_{KF}-M_{NaF})$ to the corresponding values for $Na_3AlF_6(cr)$ where M denotes heat capacity. In a similar manner, $S°(298.15\ K)$ is calculated to be 68 ± 1 $cal·K^{-1}·mol^{-1}$.

Fusion Data

T_{fus} was determined from Hall and Insley.[1]

$S°(298.15\ K) = 187.89 \pm 0.21\ J \cdot K^{-1} \cdot mol^{-1}$
T_{trs1} (β → γ) = 748 K
T_{trs2} (γ → δ) = 848 K
T_{trs3} (δ → ϵ) = 978 K
$T_{fus} = 1058 \pm 3$ K

$\Delta_f H°(0\ K) \approx -3370.9 \pm 4.6\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) \approx -3383.6 \pm 4.6\ kJ \cdot mol^{-1}$
$\Delta_{trs1} H° = [2.092]\ kJ \cdot mol^{-1}$
$\Delta_{trs2} H° = [1.255]\ kJ \cdot mol^{-1}$
$\Delta_{trs3} H° = [0.418]\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 86.19 \pm 4.2\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is derived from $\Delta_f H°(298.15\ K) = -5.4 \pm 0.5$ kcal·mol^{-1} for the reaction 3 LiF(cr) + AlF_3(cr) → Li_3AlF_6(α, β mixture). Greene *et al.*[1] obtained this result by heating the fluorides under standardized conditions in a small electrical furnace contained in their calorimeter at 25°C. $\Delta_f H°$ includes a small endothermic effect observed during heating of the reaction product. The authors suggest that the enthalpy of conversion between the α– and β– forms is small and thus their result should apply to both forms.

Heat Capacity and Entropy

Furukawa *et al.*[2] measured $C_p°$ (15–370 K) using a sample prepared by stoichiometric proportions of LiF and AlF_3 in graphite. X–ray diffraction and petrographic examination of separate portions of the sample indicated a single phase identified as β–Li_3AlF_6. The authors tabulated values of $C_p°$ and $S°$ based on their data and the extrapolation $S°(15\ K) = 0.042$ cal·K^{-1}·mol^{-1}. These values are adopted.

Douglas and Neufer[3] reported relative enthalpy data (323–973 K) for part of the same sample used in measurement of $C_p°$.[2] Their study was made prior to discovery of the five crystalline phases, and their drop–calorimetric data reveal only the transition near 748 K. Reinterpretation of the data above 748 K is complicated by the proximity of the furnace temperatures to the transition temperatures and by the tendency of high– temperature forms to revert to both α– and β– forms under different conditions of cooling. Bjorge and and Jenssen[4] and Rolin *et al.*[5] also reported crystalline enthalpy data, but these are relatively imprecise and include similar uncertainties in the final state after the drop. These difficulties preclude the derivation of accurate heat capacities for the high–temperature forms.

$C_p°$ for the β– form is adopted from,[2,3] since the two methods are in good agreement. The curve is extrapolated linearly above 748 K to obtain $C_p°$ for the high–temperature forms. Obvious differences in $C_p°$ are not apparent in the observed data for the different forms, so this should be an adequate approximation.

Transition Data

Existence of five polymorphic forms was shown by high– temperature X–ray diffraction[1,6,7] and differential thermal analysis.[6,7] Both α– and β– forms persisted at room temperature, but the α– form appeared only on quenching of high–temperature forms.[1] The α– form transformed to β near 490 K,[1,6] but the reverse transformation was not observed. Single–crystal X–ray diffraction showed the α– form to be orthorhombic.[8]

The adopted values of T_{trs} are the lowest temperatures at which the high–temperature form was observed growing at the expense of the low–temperature form.[1] DTA data[6,7] were higher by roughly 30 K for T_{trs1} and 25 K for T_{trs2}. Combination of the observed enthalpies[3] with the adopted $C_p°$ yields $\Delta_{trs1} H° = 0.76$ and $\Delta_{trs2} H° = 0.03$ or 0.15 kcal·mol^{-1}; we prefer to adopt $\Delta_{trs} H°$ values (0.5 and 0.3 kcal·mol^{-1}) which are more consistent with the areas of peaks in the DTA curve.[7] Evidence suggests that $\Delta_{trs3} H°$ is small, so we estimate 0.1 kcal·mol^{-1}.

Fusion Data

Refer to the liquid table for details.

PREVIOUS: December 1963 CURRENT: June 1970

$S°(298.15\ K) \approx [245.847]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 1058 \pm 3\ K$

$\Delta_f H°(298.15\ K) = [-3317.640]\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 86.190 \pm 4.2\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(Li_3AlF_6, l, 298.15\ K)$ is calculated from $\Delta_f H°(Li_3AlF_6, l, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus} H°$, and the difference in enthalpy, $H°(1058\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

Relative enthalpy data were measured by Bjorge and Jenssen[1] from 1065 to 1088 K and by Rolin *et al.*[2] from about 1075 to 1145 K. The data are consistent with liquid heat capacities in the range from roughly 82 to 92 $cal \cdot K^{-1} \cdot mol^{-1}$. We adopt the me[illegible]uccirclan value of 86 $cal \cdot K^{-1} \cdot mol^{-1}$ (359.824 $J \cdot K^{-1} \cdot mol^{-1}$) and extrapolate this to higher and lower temperatures. A glass transition is assumed at 750 K and $C_p°$ at lower temperatures is taken to be the same as that of β–Li_3AlF_6.

$S°(298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

T_{fus} was observed at 780°C,[3] 782°C,[2,4] 783°C[5,8] and 785°C.[1] The last and highest value is adopted for this table. Combination of the observed liquid enthalpies with the adopted crystal enthalpies yields values for $\Delta_{fus} H°$ of 19.7 $kcal \cdot mol^{-1}$ [1] (authors gave 20.2 ± 1.0) and 21.5 ± 0.3 $kcal \cdot mol^{-1}$ [2] (authors gave 21.5). We adopt the mean value of 20.6 $kcal \cdot mol^{-1}$ (86.190 $kJ \cdot mol^{-1}$) which is confirmed by values of 20.7,[8] 20.8,[4] 22.2,[4] 20.1,[4] and 22.0[2] derived from crystal–liquid phase data for binary systems. The agreement among values for $\Delta_{fus} H°$ seemingly excludes the possibility of large discrepancies in the enthalpies due to formation of the α–phase instead of β during drop–calorimetry from high temperatures.

Vaporization Data

Li_3AlF_6 vaporizes mainly to $LiAlF_4(g)$ with small contributions from species such as $Li_2AlF_5(g)$, $Li_2F_2(g)$ and LiF(g).[6,7]

Enthalpy of Formation

The heats of solution of Al(cr), NaCl(cr), and Na_3AlF_6(cr) in 4.36 m HCl acid solution were determined at 303.15 K by Coughlin.[1] The enthalpy change for the reaction Al(cr) + 2.96 NaCl(cr) + 2.96(HF·5.716 H_2O) + 3.617 H_2O(l) = $Na_{2.96}AlF_{5.96}$(cr) + 2.96(HCl·12.731 H_2O) + 3/2 H_2(g) was derived as $\Delta_r H°(298.15\ K) = -153.22 \pm 0.14$ kcal·mol. Using auxiliary $\Delta_f H°(298.15\ K)$ data from,[2,3] we obtain $\Delta_f H°((Na_{2.96}AlF_{5.96}, cr, 298.15\ K) = -787.25 \pm 0.34\ kcal·mol^{-1}$. Assuming $\Delta_r H°(298.15\ K) = 0$ for the reaction $Na_{2.96}AlF_{5.96}$ + 0.04 NaF = Na_3AlF_6, we obtain $\Delta_f H°(Na_3AlF_6, cr, 298.15\ K) = -792.76 \pm 0.4\ kcal·mol^{-1}$).

Gross *et al.*[4] measured the heat of the reaction 3/2 PbF_2(cr) + Al(cr) + 3 NaF(cr) = 3/2 Pb(cr) + Na_3AlF_6(cr) directly in a bomb calorimeter. The average heat of the reaction was found to be $\Delta_r H°(298.15\ K) = -138.3\ kcal·mol^{-1}$. Using auxiliary data [2], we obtain $\Delta_f H°(Na_3AlF_6, cr, 298.15\ K) = -794.40 \pm 1.5\ kcal·mol^{-1}$. Gross *et al.*[4] also measured the heat of reaction for 3/2 PbF_2(cr) + Al(cr) = 3/2 Pb(cr) + AlF_3(cr) as $\Delta_r H°(AlF_3, cr, 298.15\ K) = -360.99 \pm 0.31\ kcal·mol^{-1}$), we obtain $\Delta_f H°(Na_3AlF_6, cr, 298.15\ K) = -794.19 \pm 1.0\ kcal·mol^{-1}$.

Baud[6] reported $\Delta_r H° = -40.7\ kcal·mol^{-1}$ for the reaction 2 AlF_3(cr) + 6 NaF(cr) = 2 Na_3AlF_6(cr). Using auxiliary data from 2, as above, we obtain $\Delta_f H°(Na_3AlF_6, cr, 298.15\ K) = -792.8 \pm 2.0\ kcal·mol^{-1}$.

Grjotheim *et al.*[7] measured the enthalpy of mixing of 3/4 NaF(cr) + 1/4 Na_3AlF_6(cr) as $\Delta_r H°(910\ K) = -3.8 \pm 0.8\ kcal·mol^{-1}$. When this result is combined with JANAF auxiliary data for the enthalpies and $\Delta_f H°(298.15\ K)$ values from[2] we obtain $\Delta_f H°(Na_3AlF_6, cr, 298.15\ K) = -792.8 \pm 2.0\ kcal·mol^{-1}$.

The amounts of sodium over mixtures of cryolite and aluminum have been measured by Ono *et al.*,[8] Dewing,[9] and by Stokes and Frank.[10] The data have been corrected for the formation of sodium dimer by using JANAF functions for Na_2(g) and Na(g) to determine the equilibrium constants for the reaction Na_2(g) = 2 Na(g). Our evaluation of this data is presented below. We were unable to evaluate the data of Stokes and Frank[10] due to lack of appropriate data on the activities of Na_3AlF_6(l). Also shown in the table are the emf work of Dewing,[11] and the equilibrium study of Mashovets and Yudin.[12]

Our adopted value for the heat of formation of cryolite, $\Delta_f H°(Na_3AlF_6, cr, 298.15\ K) = -792.76 \pm 0.8\ kcal·mol^{-1}(-3316.91\ kJ·mol^{-1})$ is based on the study by Coughlin[1] and discussions with Dewing.[23]

Heat Capacity and Entropy

The low temperature heat capacities, 53.66–296.00 K, were measured by King.[13] The values of $C_p°$ below 53.66 K are extrapolated using the $C_p°$ equation (combination of Debye and Einstein functions) given by King. $S°(298.15\ K)$ is derived based on the low temperature heat capacities $S°(50\ K) = 3.953\ cal·K^{-1}·mol^{-1}$ and $H°(50\ K) = 0.140\ kcal·mol^{-1}$.

High temperature enthalpies have been determined by drop calorimetry by O'Brien and Kelley[14] (401.3–809.7 K), and by Albright[15] (349.99–812.70 K). The enthalpies reported by Albright are 7% higher than those reported by O'Brien and Kelley. Enthalpy data from these two calorimeters have been compared previously (see MoO_3(cr) table) indicating that the CRT calorimeter[15] results were 2% higher than the Bureau of Mines calorimeter.[14] Frank[16] commented that the enthalpies reported by O'Brien and Kelley were incorrect due to an apparent error in temperature measurement but Douglas and Ditmars[17] have questioned this correction (see NaF(cr) table for details). Our analysis indicates that the enthalpies of O'Brien and Kelley join smoothly with the low temperature $C_p°$s of King. This is not true of Albright's enthalpy data. We adopt heat capacities for the α–phase derived from the original enthalpy data reported by O'Brien and Kelley.[14]

The high temperature enthalpies have also been measured by the following investigators: Joly[18] (284.5–373.3 K), Baud[19] (289–328 K), Roth and Bertram[20] (369–802 K), Krestovnikov and Karetnikov[21] (288–1173 K), and by Lyshenko[22] (293–838 K). Their data are not used for evaluation due to inconsistencies among the reported values.

Transition Data and Fusion Data

Refer to the β–crystal table for details.

PREVIOUS: December 1968 CURRENT: December 1979

$S°$(298.15 K) = [284.881] J·K^{-1}·mol^{-1}
$T_{trs}(\alpha \rightarrow \beta)$ = 836 ± 2 K
$T_{fus}(\beta \rightarrow l)$ = 1285 ± 3 K

$\Delta_f H°$(298.15 K) = [−3288.781] kJ·mol^{-1}
$\Delta_{trs}H°(\alpha \rightarrow \beta)$ = 9.456 ± 1.7 kJ·mol^{-1}
$\Delta_{fus}H°(\beta \rightarrow l)$ = 110.039 ± 5.0 kJ·mol^{-1}

Enthalpy of Formation

$\Delta_f H°(Na_3AlF_6, cr, \beta, 298.15\ K)$ is calculated from $\Delta_f H°(Na_3AlF_6, cr, \alpha, 298.15\ K)$ by adding the enthalpy of transition, $\Delta_{trs}H°$, and the difference in enthalpy, $H°(836\ K)–H°(298.15\ K)$, between the α– and β–phases.

Heat Capacity and Entropy

High–temperature enthalpies of the β–phase have been determined by drop calorimetry by O'Brien and Kelley[1] (846.7–1263.5 K), Albright[2] (824.21–1267.17 K), and by Holm and Gronvold[3] (1070–1175 K). The data of Holm and Gronvold is in very good agreement with the data of Albright but the data of O'Brien and Kelley are systematically lower by 2%. We have already discussed the discrepancy between the data of O'Brien and Kelley and that of Albright (see the discussion on the Na_3AlF_6(cr, α) table). Our experience with the enthalpies reported by Holm, which are primarily aimed at determining heats of fusion, is that the enthalpies show a positive bias (see the $Na_5Al_3F_{14}$(cr) table) of 2–4%. For these reasons, we adopt the enthalpies from the work of O'Brien and Kelley.[1] Heat capacities derived from these enthalpies have been extended smoothly below 836 K and above 1285 K.

$S°$(298.15 K) is calculated in a manner analogous to that used for the enthalpy of formation.

Transition Data

The α–phase is the low temperature monoclinic modification of cryolite (sodium hexafluoroaluminate), space group $P2_1/n$.[4, 10] The transition to the cubic high–temperature β–phase (space group Fm3m) occurs at 836 ± 2 K. Reported values for $T_{trs}(\alpha \rightarrow \beta)$ are 823 K,[2] 832 K,[6] 833 K,[7] 833.5 K,[6] 834 K,[8] 834.5 K,[9] 837 K,[9] 838 K,[10, 11, 12] and 845 K.[1] The value of $\Delta H_{trs}H°(\alpha \rightarrow \beta)$ is calculated as the difference between the adopted enthalpies for the α– and β–phases at 836 K. Reported values of $\Delta H_{trs}H°(\alpha \rightarrow \beta)$ are (in kJ·mol^{-1}) = 5.19,[12] 9.04,[1] 9.37 ± 1.7,[9] 9.87,[9] and 9.96.[2] The cause of the discrepancies among the reported values for T_{trs}, $\Delta_{trs}H°$ and the high temperature enthalpies may be due to differences in the sample composition. The samples used have normally been hand–picked naturally occurring crystals.

Fusion Data

Our adopted value for the melting point of cryolite is 1285 ± 3 K. Reported values include (all in K): 1273,[12] 1279,[2] 1281,[7] 1282,[13, 14] 1284,[3,15] 1285,[10] 1293,[8] and 1300.[1] The value of $\Delta_{fus}H°$ is calculated as the difference between the adopted enthalpies of the β–crystal and liquid at 1285 K. Other reported values of $\Delta_{fus}H°$ are (in kJ·mol^{-1}): 69.62,[12] 106.7 ± 10.5,[15] 111.3 ± 0.8,[16] 111.75,[6] 113.4 ± 2.1,[3] 115.65,[1] and 116.77.[2]

PREVIOUS: CURRENT: December 1979

$S°(298.15\ K)$ = [286.058] $J·K^{-1}·mol^{-1}$
$T_{fus}(\beta \rightarrow l)$ = 1285 ± 3 K

$\Delta_f H°(298.15\ K)$ = [−3246.472] $kJ·mol^{-1}$
$\Delta_{fus}H°(\beta \rightarrow l)$ = 110.039 ± 5.0 $kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(Na_3AlF_6, 1298.15\ K)$ is calculated from $\Delta_f H°(Na_3AlF_6, cr, \beta, 298.15\ K)$ by adding $\Delta_{fus}H°$ and the difference in enthalpy, $H°(1285\ K) - H°(298.15\ K)$, between the β–crystal and liquid.[1]

Hong and Kleppa,[2] using a twin micro calorimeter, have determined the enthalpy of mixing for the reaction 3 NaF(l) + AlF_3(cr) = $NaAlF_6$(l) as $\Delta_r H°(1298\ K) = -10.595 \pm 0.05$ $kcal·mol^{-1}$. When this result is combined with JANAF auxiliary data and heats of formation from 3, we obtain $\Delta_f H°(Na_3AlF_6, l, 298.15\ K) = -775.1 \pm 1.0$ $kcal·mol^{-1}$.

Yudin and Mashovets[5] studied the equilibrium reaction between water vapor and cryolite (reaction B below). Results of our analysis of these studies are given below. The average of the three experimental values, $\Delta_f H°(Na_3AlF_6, l, 298.15\ K) = -776.2 \pm 1.5$ $kcal·mol^{-1}$, is in good agreement with our adopted value.

[a]Reactions:
A $Na_3AlF_6(l) = 3\ NaF(l) + AlF_3(cr)$
B $2/3\ Na_3AlF_6(l) + H_2O(g) = 1/3\ Al_2O_3(cr) + 2\ HF(g) + 2\ NaF(l)$

Heat Capacity and Entropy

The high temperature enthalpies, 1285.5–1370.5 K, were measured by O'Brien and Kelley.[6] Using their data and smoothing, we derive a constant $C_p° = 94.53\ cal·K^{-1}·mol^{-1}$ (395.514 $J·K^{-1}·mol^{-1}$) for Na_3AlF_6(l). A hypothetical glass transition is assumed at 790 K. The $C_p°$ values above 1370.5 K are obtained by linear extrapolation. $S°(298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Albright[7] meaured the high temperature enthalpies of Na_3AlF_6(l) in the temperature range 1298.1–1311.8 K. His data are systematically higher (5%) than the values determined by O'Brien and Kelley. Holm and Gronvold[8] also measured enthalpies of Na_3AlF_6(l) by drop calorimetry (1290.3–1333.1 K). Their data are intermediate between that of Albright and that of O'Brien and Kelley. For reasons discussed previously (see the Na_3AlF_6(cr, β) table), we believe both sets[7,8] are biased and have not used the data in this evaluation.

Fusion Data

Refer to the β–crystal table for details.

PREVIOUS: CURRENT: December 1979

$S°(298.15\ K) = 187.86 \pm 0.5\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = 259.5 \pm 20\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = 259.4 \pm 20\ kJ \cdot mol^{-1}$

Electronic Level and Quantum Weight		
State	ϵ_i, cm^{-1}	g_i
$^1\Sigma^+$	0	1

$\omega_e = 1682.56\ cm^{-1}$ $\omega_e x_e = 29.09\ cm^{-1}$ $\sigma = 1$
$B_e = 6.3907\ cm^{-1}$ $\alpha_e = 0.1858\ cm^{-1}$ $r_e = 1.6477$ Å

Enthalpy of Formation

Gaydon[1] extrapolated the available $X^1\Sigma$ vibrational levels, also considered predissociation in the A^1 state and concluded that the best value of $D_0°$ was 2.9 ± 0.2 ev. The linear Birge–Sponer extrapolation gave a value of 3.05 ev while the predissociation limit was 3.07 ev. The value recommended by Gaydon[1] is adopted here and leads to a value of $\Delta_f H°$(AlH, g, 298.15 K) = 62.16 ± 0 5.0 kcal·mol^{-1}, using JANAF auxiliary data.

Heat Capacity and Entropy

Zeeman and Ritter[2] examined the UV band system of AlH under high resolution and reported the molecular constants adopted above.

Ground State Quantum Weight: [1] $\sigma = 1$
Point Group: [$C_{\infty v}$]
Bond Distances: Al–O = [1.62] Å; A–H = [1.64] Å
Bond Angle: H–Al–O = [180]°
B_0 = [0.538347] cm^{-1}

Enthalpy of Formation

The enthalpy of formation is estimated by summing the constituent bond energies. The Al=O was taken as that in AlO(g) and the Al–H bond was taken as that in AlH(g); this gave a heat of atomization of 182 kcal·mol^{-1}.

Heat Capacity and Entropy

Vibrational frequencies, bond lengths and angles and point group are taken from NBS.[1]

Enthalpy of Formation

From a mass–spectrometric investigation of the equilibrium 1/3 Al_2O_3(cr) + 1/3 Al(g) + 1/2 D_2(g) = AlOD(g), Farber *et al.*[1] report second law heats of reaction of 56.7 + 0.6 kcal·mol^{-1} at 1980 K, 57.1 ± 2.8 kcal·mol^{-1} at 2060 K and 62.7 ± 1.4 kcal·mol^{-1} at 2000 K. Using JANAF auxiliary data, assuming AlOD to be AlOH, we obtain $\Delta_f H°$(AlOD, g, 298.15 K) = −44.6 ± 1, −44.0 ± 3.2 and −38.6 ± 1.8 kcal·mol^{-1}. A second equilibrium in the same investigation was Al_2O(g) + D_2O(g) = 2 AlOD(g). for which second law heats of reaction of 6.3 ± 2.1 kcal·mol^{-1} at 2060 K and 5.7 ± 0.8 kcal·mol^{-1} at 2000 K were reported. Farber *et al.*[1] also measured the heat of reaction 1/3 Al_2O_3(cr) + 4/3 Al(g) = Al_2O(g) at the same temperatures as −10.7 ± 2.8 kcal·mol^{-1} at 2060° and −10.3 ± 10.2 kcal·mol^{-1} at 2000 K. Combining these reactions and eliminating Al_2O(g) yields $\Delta_f H°$(2060 K) = −4.4 ± 5.0 kcal·mol^{-1} and $\Delta H°$(2000 K) = −5 ± 11 kcal·mol^{-1} for the reaction 1/3 Al_2O_3(cr) + 4/3 Al(g) + 2 AlOD(g).

Using auxiliary JANAF values for Al_2O_3(cr) and Al(g), $\Delta_f H°$(D_2O, g, 298.15 K) = −59.56 kcal·mol^{-1} [2] and functions for D_2O(g) from Friedman and Haar,[3] we obtain $\Delta_f H°$(AlOD, g, 298.15 K) = −43.9 ± 6 kcal·mol^{-1} and −43.4 ± 3 kcal·mol^{-1}. From all the above results we adopt a value of $\Delta_f H°$(AlOD, g, 298.15 K) = −44 ± 3 kcal·mol^{-1}, assuming that AlOH is less stable than AlOD by 1 kcal·mol^{-1} as is the case for H_2O, HDO and D_2O, we obtain $\Delta_f H°$(AlOH, g, 298.15 K) = −43 ± 3 kcal·mol^{-1}.

Farber *et al.*[1] also performed weight loss experiments under molecular flow conditions by allowing hydrogen to flow over Al_2O_3(cr). The products assumed were AlOH(g), Al(g), Al_2O(g), H(g) and H_2O(g) and the equilibrium amounts of H(g), Al(g) and Al_2O(g) were assumed to be those predicted by the free energies from the JANAF tables. A 3rd law analysis of the equilibrium constants given by Farber for the reaction 2 H_2(g) + Al_2O_3(cr) = 2 AlOH(g) + H_2O(g) yields $\Delta_f H°$(298.15 K) = 238 ± 12 kcal·mol^{-1} and $\Delta_f H°$(AlOH, g, 298.15 K) = −52 ± 6 kcal·mol^{-1}. However, the assumed equilibria involving Al_2O(g) and Al(g) may be significantly in error and thus the $\Delta_f H°$(298.15 K) should be considered as simply confirming the magnitude determined mass–spectrometrically.

Heat Capacity and Entropy

The vibrational frequencies are estimated by using the AlO(g) fundamental as approximately the Al–O stretch; the O–H stretch is that in H_2O(g); and the bending frequency is approximately the OH bend in CD_3OH(g) reported by Shimanouchi.[4]

The AlO bond length was taken from NBS,[5] and the OH bond length is assumed to be that in H_2O(g). The bond angle is assumed to be 180° using the prediction of Walsh[6] for "HAB" molecules with less than 11 valence electrons. Confirmation of this prediction is scanty for molecules having A more electronegative than B; however, Kuczkowski *et al.*[7] confirmed the linearity of KOH and CsOH which have B valence electrons.

Ground State Quantum Weight: [4] $\sigma = 1$
Point Group: [$C_{\infty v}$]
Bond Distances: Al–O = [1.90] Å; O–H = [0.96] Å
Bond Angle: Al–O–H = [180]°
Rotational Constant: B_0 = [0.412959] cm^{-1}

Enthalpy of Formation

The enthalpy of formation is obtained from $\Delta_f H°$(AlOH, g, 298.15 K) and its ionization potential, which is estimated to be 7.5 ± 1 eV (173 ± 23 kcal·mol^{-1}). The ionization potential is estimated from a reported value of 7.5 eV for the appearance potential of AlOD$^+$, presumably from the parent AlOD, by Farber *et al.*[1]

Heat Capacity and Entropy

According to the correlation diagram given by Walsh[2] for "HAB" molecules, a compound with 9 valence electrons would have the three outermost electrons is an unfilled Π orbital. Thus, it would be a $^2\Pi$ state since the molecule ought to be linear if it has less than 11 valence electrons. The outermost orbital is a bonding orbital and thus the loss of an electron from it would weaken the bonding. The vibrational frequencies are estimated from those for AlOH(g) with somewhat lower frequencies due to the weaker bonding. Similarly, the Al–O bond length is slightly increased over that in AlOH(g).

Enthalpy of Formation

The enthalpy of formation is obtained from $\Delta_f H°$(AlOH, g, 298.15 K) and its electron affinity, which is estimated to be 0.5 ± 0.9 eV (12 ± 20 kcal·mol^{-1}). The electron affinity is estimated to be small, or even negative, since the additional electron must go into an antibonding orbital, according to the correlation diagram of Walsh.[1]

Heat Capacity and Entropy

Since the molecule now has 11 valence electrons, the Walsh correlation diagram predicts a bent molecule. The extra electron is antibonding thus making the bonds weaker than in AlOH(g). The vibrational frequencies and bond lengths are taken to be the same as in $AlOH^+$(g), which is also less strongly bound than AlOH(g). The bond angle is arbitrarily chosen as 120°. The principal moments of inertia are $I_A = 0.1049 \times 10^{-39}$, $I_B = 6.4867 \times 10^{-39}$, and $I_C = 6.5917 \times 10^{-39}$ g·cm^2.

Enthalpy of Formation

The hydroxyl group can often be considered as intermediate between F and Cl as is illustrated by the following examples of bond energies from these tables. $D_0°$(F–H) = 136 kcal·mol^{-1}, $D_0°$(Cl–H) = 103 kcal·mol^{-1} and $D_0°$(HO–H) = 119 kcal·mol^{-1}; also, $D_0°$(F–BO) = 163 kcal·mol^{-1}, $D_0°$(Cl–BO) = 105 kcal·mol^{-1} and $D_0°$(HO–BO) = 143 kcal·mol^{-1}. Thus from $D_0°$(F–AlO) = 181 kcal·mol^{-1} and $D_0°$(Cl–AlO) = 134 kcal·mol^{-1}, we estimate $D_0°$(HO–AlO) = 158 ± 20 kcal·mol^{-1}. This yields $\Delta_f H°$(HOAlO, g, 298.15 K) = −127 ± 20 kcal·mol^{-1}.

Consider also $D_0°$(FB–O) = 175 kcal·mol^{-1} and $D_0°$(ClB–O) = 169 kcal·mol^{-1}; and $D_0°$(FAl–O) = 138 kcal·mol^{-1} and $D_0°$(ClAl–O) = 132 kcal·mol^{-1}; it is evident that the substituent F or Cl has little effect on the B–O and Al–O bonds. Thus, we assume that $D_0°$(HOAl–O) = 135 ± 10 kcal·mol^{-1} which leads to $\Delta_f H°$(HOAlO, g, 298.15 K) = −119 ± 10 kcal·mol^{-1}.

Farber *et al.*[1] found no evidence for the ion $DOAlO^+$ when reacting $D_2O(g) + Al_2O_3(cr)$. Form estimates of the pressure needed to ensure detection of DOAlO and a knowledge of the D_2O pressure, they calculated the most negative value of $\Delta_f H°$(HOAlO, g, 298.15 K) = −104 ± 10 kcal·mol^{-1}. The absence of $DOAlO^+$ may be caused by fragmentation by the ionizing electrons and thus the value quoted may not be a real limit.

We adopt $\Delta_f H°$(HOAlO, g, 298.15 K) = −110 ± 15 kcal·mol^{-1} which encompasses all the values.

Heat Capacity and Entropy

Vibrational frequencies, bond distances, bond angles, and the product of the moments of inertia are taken from NBS.[2] The principal moments of inertia are: $I_A = 0.1301 \times 10^{-39}$, $I_B = 16.9121 \times 10^{-39}$, and $I_C = 17.0422 \times 10^{-39}$ g·cm^2.

PREVIOUS: December 1968 (1 atm) CURRENT: December 1968 (1 bar)

$S°(298.15\ K) = [87.86 \pm 0.4]\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) =$ Unknown

$\Delta_f H°(298.15\ K) = -117.15 \pm 8.4\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The heats of solution of $LiAlH_4$(cr) in HCl(aq) were measured calorimetrically by Davis *et al.*,[1] Fasolino *et al.*,[2] and Smith and Bass.[3] The results are given in the following table.

Source	Reaction	$\Delta_r H°(298.15\ K)$ kcal·mol^{-1}
Davis *et al.*[1]	(1) $LiAlH_4$(cr) + 10 HCl(aq, 50 H_2O) → [LiCl + $AlCl_3$ + 6 HCl](aq, 500 H_2O) + 4 H_2(g)	−165.87
	(2) [$AlCl_3$ + LiCl + 6 HCl](aq, 500 H_2O) + 41020 H_2O(l) → [$AlCl_3$ + LiCl + 6 HCl](aq, 41520 H_2O)	−4.43
	(3) [$AlCl_3$ + LiCl + 6 HCl](aq, 41520 H_2O) → [$AlCl_3$ + LiCl + 6 HCl](aq, 5190 H_2O)	0.00(assumed)
	(1) + (2) + (3)	−170.30
Fasolino *et al.*[2]	(4) Al + 60 HCl(aq, 14 H_2O) → [$AlCl_3$ + 57 HCl](aq, 840 H_2O) + 3/2 H_2(g)	−128.14
	(5) Li + 60 HCl(aq, 14 H_2O) → [LiCl + 59 HCl](aq, 840 H_2O) + 1/2 H_2(g)	−67.05
	(6) $LiAlH_4$(cr) + 60 HCl(aq, 14 H_2O) → [LiCl + $AlCl_3$ + 56 HCl](aq, 840 H_2O) + 4 H_2(g)	−170.52
	(4) + (5) − (6)	−24.67
Smith and Bass[3]	(7) $LiAlH_4$(cr) + 39.715 HCl(aq, 11.624 H_2O) → [LiCl + $AlCl_3$ + 35.715 HCl](aq, 12.926 H_2O) + 4 H_2(g)	−164.6
	(8) LiCl(cr) + [$AlCl_3$ + 35.715 HCl](aq, 12.926 H_2O) → [LiCl + $AlCl_3$ + 35.715 HCl](aq, 12.926 H_2O)	−6.75
	(7) − (8)	−157.85

Incorporating appropriate thermal data, the values for $\Delta_f H°(LiAlH_4, cr, 298.15\ K)$ were derived as −28.51 (recalculated value, by Smith and Bass),[3] −24.67 ± 1.31 and −28.4 ± 1.5 kcal·mol^{-1}, respectively. The adopted value, −28.0 ± 2.0 kcal·mol^{-1} (−117.152 ± 8.4 kJ·mol^{-1}), is the weighted average of the above three values.

Heat Capacity and Entropy

Bonnetot *et al.*[4] measured $C_p°$ in the region 15 to 308 K. Our adopted thermal functions at 300 K and below are based on the smoothed values and integration by those authors using $S°(15\ K) = 0.10\ J \cdot K^{-1} \cdot mol^{-1}$. Above 300 K we have used $C_p°$ values estimated by comparison with those for $LiBH_4$(cr), $LiBO_2$(cr) and $LiAlO_2$(cr).[5]

Decomposition Data

T_{dcm}(410 ± 10 K) was reported by Finholt *et al.*[6] The decomposition products are aluminum, hydrogen, and lithium hydride. This reaction is apparently kinetically controlled since the Gibbs free energy for the decomposition is negative even at room temperature.

Enthalpy of Formation

Gaydon,[1] Rosen[2] and Huber and Herzberg[3] reference the analysis by Barrow[4] for values of the dissociation energy of AlI(g). Barrow[4] reports $D_0^o = 364.0\ kJ \cdot mol^{-1}$ from an analysis of fluctuation bonds in the AlI spectrum. Martin and Barrow[5] report a value of $365.97 \pm 1.92\ kJ \cdot mol^{-1}$ for the dissociation energy of AlI based on previous observations of the $A^1 - X^1\Sigma^+$continuum and calculated potentials for these states. Our adopted dissociation energy is the average of these values, $365.01 \pm 0.21\ kJ \cdot mol^{-1}$, and yields $\Delta_f H°$(AlI, g, 298.15 K) = $67.95 \pm 4.18\ kJ \cdot mol^{-1}$.

Heat Capacity and Entropy

Molecular and spectroscopic constants are based on the analysis of electronic spectra published by Martin and Barrow.[5] The constants are in excellent agreement with those from earlier studies.[6,7] The electronic states are taken from Rosen[2] with the exception of the upper $^3\Pi$ state and the $b^3\Sigma^+$ state. The upper $^3\Pi$ state is estimated to be approximately in a linear relationship with the two lower $^3\Pi$ states. The $b^3\Sigma^+$ state is assigned by analogy with AlF, AlCl and AlBr, JANAF Thermochemical Tables, 3rd ed.[8]

$S°(298.15\ K) = [196.10]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 464.15 \pm 0.2\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -302.9 \pm 2.0\ kJ·mol^{-1}$
$\Delta_{fus} H° = 15.9 \pm 1.3\ kJ·mol^{-1}$

Enthalpy of Formation

Literature values for the enthalpy of formation of AlI_3(cr) are based on solution calorimetry measurements and differ considerably in magnitude. The heat of solution of the crystal in H_2O at 298.15 K was measured by Dear and Eley[1] and reported as $-91.4 \pm 1.5\ kcal·mol^{-1}$. Adopting CODATA's[2] values for the enthalpies of formation of the aqueous ions, this yields $\Delta_f H°(AlI_3, cr, 298.15\ K) = -78.0 \pm 2.0\ kcal·mol^{-1}$. This estimate is undoubtedly high because of hydrolysis of the salt.

More reliable measurements have been attempted in aqueous acid and base. Klemm and Tanke[3] measured the heat of solution of AlI_3(cr) at 273 K in aqueous HCl. Using auxiliary data including estimated heat capacities, they reported $\Delta_f H°(AlI_3, cr, 298.15\ K) = -70.6 \pm 0.7\ kcal·mol^{-1}$. Efimov, Kislova and Medvedev[4] measured the heat of solution of AlI_3(cr) in an aqueous HCl solution containing KCl(cr) and the heat of solution of $AlCl_3$(cr) in an aqueous HCl solution containing KI(cr). From these heats of solution measurements and using the heats of formation of $AlCl_3$,[5] KCl[6,7] and KI[6,8] as auxiliary data, they obtained $\Delta_f H°(AlI_3, cr, 298.15\ K) = -72.4 \pm 0.5\ kcal·mol^{-1}$. In a similar study, Anthoney *et al.*[9] measured the heat of solution of AlI_3(cr) and $AlCl_3$(cr) in an aqueous alkaline solution containing dissolved sodium halides. They reported $\Delta_f H°(AlI_3, cr, 298.15\ K = -67.0 \pm 0.6\ kcal·mol^{-1}$.

Corbett and Gregory[10] investigated the equilibrium $AlI_3(cr) + 3\ HCl(g) \rightarrow AlCl_3(cr) + 3\ HI(g)$ and reported $\Delta_r G°(298.15\ K) = -8.7 \pm 0.2\ kcal·mol^{-1}$. Using auxiliary data, the derived heat of reaction is $-10.7 \pm 0.2\ kcal·mol^{-1}$ and the heat of formation of AlI_3, $\Delta_f H°(AlI_3, cr, 298.15\ K)$ is evaluated to be $-73.6 \pm 0.8\ kcal·mol^{-1}$. The value reported by Efimov *et al.*[4] is chosen as most reliable and is adopted for the heat of formation.

Heat Capacity and Entropy

The heat capacities, 298.15–464 K, were taken from Kelley,[11] whose values were derived from the enthalpy data measured by Fischer.[12] Above 464 K the $C_p°$ values are obtained by graphical extrapolation. The entropy, $S°(AlI_3, cr, 298.15\ K)$, is calculated from $S°(AlI_3, l, 298.15\ K)$ by subtracting $\Delta_{fus}S°$ and the difference between $S°(464.15\ K) - S°(298.15\ K)$ for crystal and liquid.

Fusion Data

The temperature and enthalpy of melting were measured by Fischer.[12]

Sublimation Data

The enthalpy of sublimation, $\Delta_{sub} H°(298.15\ K) = 116.3\ kJ·mol^{-1}$ for the process $2\ AlI_3(cr) = 2\ Al_2I_6(g)$, is calculated from vapor pressure data reported by Fischer, Rahlfs and Benze[13] by both the 2nd and 3rd law methods. Refer to the Al_2I_6(g) table for details.

PREVIOUS: June 1964 CURRENT: September 1979

$S°(298.15\ K) = [223.648]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 464.15 \pm 0.2\ K$

$\Delta_f H°(298.15\ K) = [-289.444]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 15.9 \pm 1.3\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(AlI_3, l, 298.15\ K)$ is calculated from $\Delta_f H°(AlI_3, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus} H°$, and the difference in enthalpy, $H°(464.15\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The heat capacities, 464–500 K, were taken from Kelley,[1] whose values were derived from the enthalpy data measured by Fischer.[2] The $C_p°$ values above 500 K were assumed to be the same as that at 500 K. $S°(298.15\ K)$ is estimated so that the values of $\Delta_{vap} H°$ calculated from vapor pressure data by the 2nd and 3rd law methods are in reasonable agreement. Refer to the Al_2I_6(g) table for details.

Fusion Data

The temperature and enthalpy of melting were reported by Fischer.[2]

Enthalpy of Formation

Fischer, Rahlfs and Benze[1] have determined the equilibrium constants for the reaction $Al_2I_6(g) = 2\ AlI_3(g)$ from vapor density measurements. The heats of reaction are calculated from these data using both 2nd and 3rd Law methods. The results are summarized below:

	Data	$\Delta_f H°$(298.15 K), $kcal \cdot mol^{-1}$ Al_2I_6		Drift	$\Delta_f H°$(298.15 K)
T/K	Points	2nd law	3rd law	$cal \cdot K^{-1} \cdot mol^{-1}$	$kcal \cdot mol^{-1}$
656–819	11[a]	24.39 ± 0.5	24.56 ± 0.2	0.2 ± 0.6	−46.2

[a]Points at 614.15, 644.15, 843.15 rejected due to statistical test.

The adopted value, $\Delta_f H°(AlI_3, g, 298.15\ K) = -46.2 \pm 2.0\ kcal \cdot mol^{-1}$ ($-193.3 \pm 8.4\ kJ \cdot mol^{-1}$), is based on the 3rd law enthalpy of reaction and $\Delta_f H°(Al_2I_6, g, 298.15\ K) = -489.5 \pm 8.4\ kJ \cdot mol^{-1}$.

Heat Capacity and Entropy

The molecular structure, bond distances and angles were taken from the electron diffraction work reported by Shen.[2] These values are in good agreement with those determined by Akishin, Rambidi and Zasorin.[3] Beattie and Horder[4] studied the gas phase Raman spectra of monomeric AlI_3 and reported $\nu_1 = 156\ cm^{-1}$ and $\nu_4 = 64\ cm^{-1}$. The other vibrational frequencies were adjusted not only for consistency with the frequencies chosen for AlF_3(g), $AlCl_3$(g) and $AlBr_3$(g)[5] but also for agreement between the 2nd and 3rd Law $\Delta_f H°(298.15\ K)$ in the data set tabulated above. The principal moments of inertia are $I_A = 189.5840 \times 10^{-39}$, $I_B = 189.5841 \times 10^{-39}$, and $I_C = 379.1681 \times 10^{-39}\ g \cdot cm^2$.

PREVIOUS: September 1979 (1 atm) CURRENT: September 1979 (1 bar)

$S°(298.15\ K) = 53.31 \pm 1.2\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 1973 \pm 15\ K$

$\Delta_f H°(0\ K) = -1180.52 \pm 2.1\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1188.67 \pm 2.1\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = [87.864 \pm 21]\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The adopted enthalpy of formation is based on the solution calorimetric studies of Coughlin.[1] From measurements of the heat of solution of $LiAlO_2$(cr) in aqueous HCl and of four auxiliary reactions, Coughlin reported $\Delta_r H°(303.15\ K) = -89.12 \pm 0.14\ kcal \cdot mol^{-1}$ for Al(cr) + LiCl(cr) + 14.731 H_2O(l) → $LiAlO_2$(cr) + HCl·12.731 H_2O(aq) + 3/2 H_2(g). This value is corrected to $\Delta_r H°(298.15\ K) = -88.9 \pm 0.14$ $kcal \cdot mol^{-1}$ using heat capacities of the materials. This value, when combined with auxiliary heats of formation[2,3] yields our adopted value of $\Delta_f H°(LiAlO_2, cr, 298.15\ K) = -284.1 \pm 0.5\ kcal \cdot mol^{-1}$ ($-1188.674\ kJ \cdot mol^{-1}$).

Gross *et al.*[4] measured the heats of solution of $LiAlO_2$(cr) and of $Al_2O_3 3\ H_2O$(cr, gibbsite) + Li_2O(cr) in aqueous HF. From these and the heat of solution of three moles of H_2O in HF(aq) they report $\Delta_r H°(298.15\ K) = -11.3\ kcal \cdot mol^{-1}$ for Li_2O(cr) + $Al_2O_3 3\ H_2O$(cr, gibbsite) → 2 $LiAlO_2$(cr) + 3 H_2O(l). Combining this $\Delta_r H°$ with auxiliary heats of formation[2,5] yields $\Delta_f H°(LiAlO_2, cr, 298.15\ K) = -283.8 \pm 0.7$ $kcal \cdot mol^{-1}$, in excellent agreement with the adopted value.

Equilibrium studies of vapor pressure over $LiAlO_2$(cr) by the torsion effusion technique support the adopted value of $\Delta_f H°(298.15\ K)$. Potter *et al.*[6] and Popkov and Semenov[7] both studied the equilibrium $LiAlO_2$(cr) → Li(g) + $x/4\ O_2$(g) + $(1-x)/2$ O(g) + 1/2 Al_2O_3(cr, α) in the temperature range from 1500 to 1820 K where $1-x \cong 0.13$. Neither author reports the raw data but they do report 2nd and 3rd law values for $\Delta_r H°(298.15\ K)$. Based on these reported values and auxiliary $\Delta_f H°(298.15\ K)$ data[2] we calculate 2nd and 3rd law values for $\Delta_f H°(LiAlO_2$, cr, 298.15 K) of −283.9 and −282.8 $kcal \cdot mol^{-1}$, respectively, from the data of Potter *et al.*[6] 2nd and 3rd law values for $\Delta_f H°(298.15\ K)$ calculated from the results of Popkov and Semenov[7] are −283.8 and −277.9 $kcal \cdot mol^{-1}$, respectively. The expected uncertainty in these determinations is of the order of 2 to 5 $kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The adopted values of $C_p°$ below 300 K are taken from Douglas and Beckett[8] based on the low temperature $C_p°$ measurements of King (53–296 K).[9] At higher temperatures the adopted $C_p°$ data are based on the drop calorimetric enthalpy data of Christensen *et al.* (399–1795 K).[10] No transitions were detected in either study.

Phase Data

The data in this table are for the γ or tetragonal phase of $LiAlO_2$. The crystal structure is $P4_12_12$.[11,12] A hexagonal (α) phase may be prepared but converts to the γ phase on heating. Byker *et al.*[13] recently reviewed the phase data and constructed a phase diagram for the Al_2OLi_2O system. The reader is referred to their paper for details but the following comments may be informative. The α to γ phase transformation occurs above 1173 K but may occur at lower temperature. The transition has frequently been reported as irreversible although Lejus and Collongues[14] report that the γ to α transformation does occur if aided by prolonged grinding. Measurements of the heat of the α–γ transition are hampered by its slow nature but apparently imply that it is slightly exothermic near 1200 K. Based on the above data and the known density change between α and γ phases, Byker *et al.* constructed a phase diagram which indicates that the α phase is the thermodynamically stable phase below −550 K at 1 atm pressure. This seems to support the observation of Lejus and Collongues. The uncertainties are such that this temperature may be off by several hundred Kelvin. Thus, while it is clear that the γ phase is the thermodynamically stable phase above 1200 K, its stability at low temperature may be controlled by kinetic factors.

Fusion Data

Refer to the liquid table for details.

PREVIOUS: June 1972 CURRENT: December 1979

$S°(298.15\ K) = [93.711]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1973 \pm 15\ K$

$\Delta_f H°(298.15\ K) = [-1107.739]\ kJ·mol^{-1}$
$\Delta_{fus}H° = [87.864 \pm 21]\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(LiAlO_2, l, 298.15\ K)$ is calculated from $\Delta_f H°(LiAlO_2, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus}H°$, and the difference in enthalpy, $H°(1973\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The heat capacity of $LiAlO_2$(l) is estimated to be 30 $cal·K^{-1}·mol^{-1}$ (125.52 $J·K^{-1}·mol^{-1}$) above a hypothetical glass transition temperature of 1450 K. Below this temperature the heat capacity is taken to be the same as the crystal. The adopted $C_p° = 30\ cal·K^{-1}·mol^{-1}$ is based on an estimated value of $C_p° = 7.5\ cal·K^{-1}·g·atom^{-1}$ recommended by Kubaschewski and Alcock.[2] $S°(298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy formation.

Fusion Data

The adopted melting point, $T_{fus} = 1973 \pm 15$ K, is based on the phase study of Strickler and Roy[3] and is suppported by the value 1975 K reported by Prophet.[4] The older study of Ballo and Dittler[5] reported T_{fus} to lie between 2173 and 2273 K and Hummel *et al.*[6] reported $T_{fus} = 1883 \pm 15$ K. Hummel *et al.* also stated that their samples were only partially fused after considerable time at 1973 K. Prophet also reported that his samples slowly decomposed on fusion and that successive melting points approached that of aluminum oxide at 2308 K. After fusing seven times X-ray analysis indicated the sample was 95% α-aluminum oxide and 5% $LiAl_5O_8$ with Li_2O being lost by vaporization. The adopted $\Delta_{fus}H°$ is estimated by assuming the entropy of melting to be approximately the same on a gram-atom basis as that of $BeAl_2O_4$.[1]

$S°(298.15\ K) = 20.14 \pm 0.21\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = -312.98 \pm 2.5\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -317.98 \pm 2.5\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The adopted enthalps of formation is the average value of the calorimetric determinations of Neugebauer and Margrave[1] and Mah *et al.*[2] Neugebauer and Margrave obtained $\Delta_f H°(298.15\ K) = -76.47 \pm 0.2$ kcal·mol^{-1} by direct nitridation. Mah *et al.* obtained $\Delta_f H°(298.15\ K) = -75.6 \pm 0.4$ kcal·mol^{-1} via oxygen combustion calorimetry. The older direct nitridation study of Neumann *et al.*[3] yields $\Delta_f H°(298.15\ K) = -57.4 \pm 0.8$ kcal·mol^{-1}; the source of bias in this study is not apparent. Fichter and Jenny[4] also made measurements using oxygen combustion calorimetry; our recalculation of their data using the modern accepted value for the heat of formation of Al_2O_3(cr, α)[5] yields $\Delta_f H°(298.15\ K) = -71.5 \pm 1.0$ kcal·mol^{-1}.

Equilibrium data supports the calorimetric determinations but is less certain due largely to corrections for a condensation coefficient significantly different from unity. We have adopted a condensation coefficient (fraction of incident molecules which condense on the vaporizing surface) of $\alpha = 2 \times 10^{-3}$ from Hildenbrand and Hall[6] and used that value to convert measured pressures to equilibrium pressures, $P_e = P_m/\alpha$. This is a large correction, equivalent in some cases to 50 kcal·mol^{-1} in the $\Delta_f H°(298.15\ K)$ values. The data below corresponds to the dissociation of 2 AlN(cr) = 2 Al(g) + N_2(g).

[a] Raw pressure data corrected using $\alpha = 2 \times 10^{-3}$
[b] Two points rejected by a statistical test.
[c] One point rejected by a statistical test.

Studies not re-evaluated above include those of Blank[11] and Wu.[12] Blank's[11] Knudsen and Langmuir effusion studies yield a third law value of $\Delta_f H°(298.15\ K) = -306.4$ kcal·mol^{-1} ($\Delta_f H°$(AlN, cr, 298.15 K) = −74.4 kcal·mol^{-1}) when corrected for condensation coefficient according to the author. We have not reanalyzed this data since not all of the measured points from the graph are given in tabular form. Wu's Knudsen effusion study[12] leads to a value of $\Delta_f H°(AlN, cr, 298.15\ K) = -62.2 \pm 1.1$ kcal·mol^{-1} as reported by the author based on a second-law analysis. The data are presented graphically only. Wu also suggests that AlN decomposes incongruently with loss of N_2 until a composition of Al_2N is reached.

Heat Capacity and Entropy

The adopted heat capacity data is derived by using orthogonal polynomials to smoothly merge the heat capacity–enthalpy data of Mah *et al.*[2] These authors reported heat capacity data in the 53–296 K range and enthalpy data (via drop calorimetry) in the 399–1799 K range. The entropy is based on $S°(50\ K) = 0.0692$ cal·K^{-1}·mol^{-1}. The $C_p°$ data above 1799 K are a smooth extrapolation of the merged data and will approach a constant $C_p° = 12.521$ cal·K^{-1}·mol^{-1} at very high temperature. Demidenko *et al.*[13] measured heat capacity over the range 55 to 330 K and their values for $S°(298.15\ K) = 4.804$ cal·K^{-1}·mol^{-1} and $H°(298.15\ K) - H°(0\ K) = 925$ cal·K^{-1}·mol^{-1} are in excellent agreement with the adopted values; their complete data are not available. Mezaki *et al.*[14] measured enthalpies via drop calorimetry over the range 478 to 1113 K; their values are −1.5% lower than the adopted values.

Enthalpy of Formation

The enthalpy of formation is calculated from the adopted dissociation energy using auxiliary JANAF data.[1] Simmons and McDonald[2] observed an apparent predissociation from the J=47 rotational level during their emission spectroscopic study of AlN. They have shown that it is possible to assign this predissociation as being from the excited $^3\Pi$ state of AlN(g) to ground state Al(g) + N(g). If this assignment is correct, we calculate $D_0° = 21{,}000\ cm^{-1}$ using their value of $B_o = 0.5811\ cm^{-1}$ for the excited $^3\Pi$ state rotational constant. A linear Birge–Sponer extrapolation using the adopted molecular constant data yields $D_0° = 25{,}000\ cm^{-1}$. Considering the nature of the uncertainties in these calculations, we adopt an average value of $D_0° = 23{,}000 \pm 3{,}000\ cm^{-1}$ or $D_0° = 66 \pm 9\ kcal \cdot mol^{-1}$. With auxiliary JANAF data[1] this yields an adopted value of $\Delta_f H°(298.15\ K) = 125 \pm 9\ kcal \cdot mol^{-1}$ ($523.000 \pm 38\ kJ \cdot mol^{-1}$).

Heat Capacity and Entropy

The adopted molecular constant data are taken from the emission spectroscopy work of Simmons and McDonald[2] except for $\omega_e x_e$ which we estimate from the Pekeris relationship $\omega_e x_e = B_e(1 + \omega_e \alpha_e / 6B_e^2)$.[2,3] Although the energy difference between the two $^3\Pi$ states is well established, it is not certain that the lowest $^3\Pi$ state is the ground state since it has only been studied in emission. We assume it to be the ground state by analogy with the BN molecule where the $^3\Pi$ state has been shown theoretically and experimentally (via absorption spectroscopy) to be the ground state.[4] For BN, SCF calculations[5] indicate $^3\Sigma$, $^1\Sigma$ and $^1\Pi$ states lying between 3400 and 4800 cm^{-1}. If these states lie at the same energy for AlN, they would have no effect on the thermochemical properties below 500 K but would increase the entropy at 6000 K by 5.0 $J \cdot K^{-1} \cdot mol^{-1}$.

$S°(298.15\ K) = 70.40 \pm 0.04\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{trs} = 740\ K$
$T_{fus} = > 1923\ K$

$\Delta_f H°(0\ K) = -1137.32 \pm 0.71\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1133.19 \pm 0.71\ kJ \cdot mol^{-1}$
$\Delta_{trs} H° = 1.297\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° =$ Unknown

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ was reported by Coughlin.[1] The value was calculated from the measured heat of solution of $NaAlO_2$(cr) at 303.15 K in 4.360m hydrochloric acid solution.

Heat Capacity and Entropy

The low temperature heat capacities, below 350 K, were measured by Westrum.[2] Heat capacities above 350 K, 399.4–1698.6 K, were measured by Christensen *et al.*[3] These two sets of $C_p°$ data were plotted graphically and joined smoothly at 350 K. Low temperature heat capacities 51 K–298.15 K, were also determined by King[4] and agree very well with those reported by Westrum.[2] $S°(298.15\ K)$ was reported by Westrum[2] based on $S°(10\ K) = 0.01\ J \cdot K^{-1} \cdot mol^{-1}$.

Transition Data

T_{trs} and $\Delta_{trs} H°$ were obtained from Christensen *et al.*[3]

Fusion Data

T_{trs} is taken from Kammermeyer *et al.*[5]

Enthalpy of Formation

We adopt $\Delta_f H°(298.15\ K) = 16.0 \pm 2$ kcal·mol^{-1} ($D_0° = 121.193 \pm 2$ kcal·mol^{-1}) based mainly on $D_0° \geq 121.0 \pm 0.6$ kcal·mol^{-1} [5] from laser-induced fluorescence of AlO and on $D_0° = 122.0 \pm 2.5$ and 121.6 kcal·mol^{-1} [6] from recent mass spectrometry of the evaporation of Al_2O_3. The mass-spectrometric values of $D_0°$[6] become 121.5 ± 3 and -120.8 ± 3 kcal·mol^{-1} when we convert to $\Delta_f H°(298.15\ K) = 78.8 \pm 1.0$ kcal·mol^{-1} for Al(g) and to a temperature scale based on $T_{fus} = 2327$ K for $\alpha-Al_2O_3$ instead of 2318 K.

The adopted $\Delta_f H°$ was selected by Pedley and Marshall[7] from a network analysis of thermochemical data on $D_0°$ of AlO, BO, BaO, SiO and TiO. They considered over two dozen studies on AlO plus many studies on related oxides. We concur in their selection.

Our previous JANAF Thermochemical Table[8] summarized older mass-spectrometric values of $D_0°$ ranging from 113.5 to 119.9 kcal·mol^{-1}. We now give less weight to the lower values for two reasons: they are less consistent with the network of data for other oxides and they all may have a negative bias arising from ionization cross sections. These lower values converge toward the adopted value if they are recalculated using alternative approximations for ionization cross sections[9–11] of reactants and calibrants. Ho and Burns[6] and Drowart[11] gave some examples of similar recalculations. We conclude that errors in cross sections provide a plausible, though unproved, explanation of much of the discrepancy between the mass-spectrometric and fluorescence values of $D_0°$. Errors in the interpretation of fluorescence data[5] appear to be less likely, though not impossible. Plausibility of the fluorescence interpretation rests in part on the spectroscopic limit $D_0° \leq 122.1 \pm 0.6$ kcal·mol^{-1} derived by Drowart[11] from reinterpretation of absorption edges observed by Tyte and previously interpreted to give $D_0° \leq 119.9$ kcal·mol^{-1}.[12] Additional results on $D_0°$ have been summarized elsewhere.[5] Gurvich *et al.*[13] selected $D_0° = 121.176 \pm 1.2$ kcal·mol^{-1}.

Heat Capacity and Entropy

Electronic levels (ν_{oo}) and vibration–rotation constants of the observed states are from Huber and Herzberg[1] and recent studies.[2] Schamps[3] made extensive predictions of the unobserved levels of AlO and MgO. We adopt these estimates since additional data for MgO[4] and the F state of AlO confirm that they are reasonably accurate. Estimated molecular constants are derived from isoconfigurational levels whenever possible. We omit levels above 40187 cm^{-1} since they will have a negligible effect. The thermodynamic functions are calculated using first-order anharmonic corrections to Q_r^i and Q_r^i in the partition function $Q = Q_t \Sigma\, Q_v^i Q_r^i g_i \exp(-c_2\epsilon_i/T)$. Functions calculated by Gurvich *et al.*[13] are in close agreement; their values of the Gibbs energy function differ by ≤ 0.01 at $T \leq 5000$ K and by only 0.026 cal·K^{-1}·mol^{-1} at 6000 K.

Enthalpy of Formation

$\Delta_f H°$ is calculated from that of AlO[1] using Hildenbrand's appearance potential[2] of 9.53 ± 0.15 eV (219.8 ± 3.5 $kcal \cdot mol^{-1}$), assuming that it is identical with the ionization potential for $AlO(g) \rightarrow AlO^+(g) + e\ (g)$. Other reported values for the appearance potential range from 9 to 10.3 ± 1 eV, including several values of 9.5.[3-5] These values are consistent with, but less precise than, the adopted value. $\Delta_f H°(0\ K)$ yields $D_0° = 39.5 \pm 5$ kcal·mol for $AlO^+ \rightarrow Al^+ + O$; this is larger than the value of −26 $kcal \cdot mol^{-1}$ predicted by Schamps[6] from his SCF calculation of IP(AlO) = 10.08 eV. MNDO calculations[7] differ by only 3.5 $kcal \cdot mol^{-1}$ from our $[\Delta_f H°(AlO^+, 298.15\ K) - \Delta_f H°(AlO, 298.15\ K)]$ even though the MNDO values of $\Delta_f H°(298.15\ K)$ deviate by −14 and −18 $kcal \cdot mol^{-1}$, respectively.

$\Delta_f H°(AlO^+, g, 298.15\ K)$ is obtained from $\Delta_f H°(AlO)$ by using IP(AlO) with JANAF [1] enthalpies, $H°(0\ K) - H°(298.15\ K)$, for AlO(g), $AlO^+(g)$ and $e^-(g)$. $\Delta_r H°(Al0 \rightarrow A10^+ + e^-, 298.15\ K)$ differs from a room-temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[5] $\Delta_f H°(298.15\ K)$ should be changed by −1.481 $kcal \cdot mol^{-1}$ if it is to be used in the ion convention that excludes the enthalpy of the electron.

Heat Capacity and Entropy

No spectroscopic data have been observed for AlO^+ but Schamps[6] recently predicted electronic levels and molecular constants from variational calculations with semiempirical estimates of correlation energy differences. Similar calculations were reasonably accurate for MgO.[6] The predictions for AlO^+ yield almost equal energies for $^3\Pi$ and $^1\Sigma^+$; thus they do not distinquish which is the ground state. AlO^+ is isoelectronic with MgO and AlN. MgO has a $^1\Sigma^+$ ground state with the low-lying $^3\Pi$ level at 2600 cm^{-1}.[8] Triplet-triplet bands are observed for AlN[9, 10] and it is quite likely that the lower $^3\Pi$ level is the ground state.[10] We conclude for AlO^+ that $^3\Pi$ is very low lying and probably the ground state; it will dominate the electronic partition function.

The adopted electronic levels are minor modifications of the predictions of Schamps.[6] Molecular constants of the $^3\Pi$ state are estimated to be intermediate between those of MgO[1] and AlN.[9] The r_e adopted for $^3\Pi$ is −0.1 Å longer than that of Al_2O.[1] Values of r_e adopted for AlO^+ are also longer than those of their Π and Σ counterparts in AlO.[1] Values of ω_e are based on force-constant comparisons. Other constants are based on comparisons with the observed and calculated values for MgO.[1, 6]

The low-lying electronic levels cause an entropy uncertainty of perhaps 3 $cal/(mol \cdot K)^{-1}$ at 298 K but <1 $cal/(mol \cdot K)^{-1}$ at T>2000 K. Uncertainty in the enthalpy is large (perhaps 4 $kcal \cdot mol^{-1}$) at high temperature. The thermodynamic functions are calculated using first-order anharmonic corrections to Q_t^i and Q_v^i in the partition function $Q = Q_t \Sigma Q_t^i Q_v^i g_i \exp(-c_2 \epsilon_i / T)$.

Enthalpy of Formation

We adopt $\Delta_f H°(0\ K) = -62.9 \pm 4\ kcal·mol^{-1}$ based on equilibrium data for $AlO(g) + Cl^-(g) = Cl(g) + AlO^-(g)$ obtained using effusion mass spectrometry by Srivastava *et al.*[1, 2] Our analysis of the data is summarized below. For the process $AlO^-(g) \rightarrow Al(g) + O^-(g)$ we calculate a dissociation energy $D_0° = 166.4 \pm 4\ kcal·mol^{-1}$; this is comparable to $D_0°(AlF) = 159.3 \pm 1.5\ kcal·mol^{-1}$ [3] and much larger than $D_0°(AlO) = 121.2 \pm 2\ kcal·mol^{-1}$.[3] The corresponding electron affinity, EA(AlO) = 78.9 ± 4 kcal·mol^{-1} (3.42 eV), is 4.4 kcal·mol^{-1} less than EA(Cl) = 83.3 kcal·mol^{-1}.[3] Gaines and Page[4] used a semi-empirical method to predict EA(AlO) = 60 and EA(BO) = 49 kcal·mol^{-1}, corresponding to a difference of 11 kcal·mol^{-1}. Although this difference is comparable with the experimental difference of 9 kcal·mol^{-1}, the values predicted for EA(AlO) and EA(BO) are −20 kcal·mol^{-1} lower than the experimental results.[1, 2] MNDO calculations[5] predicted $\Delta_f H°(298.15\ K) = -55.9$ and $[\Delta_f H°(AlO^-, 298.15\ K) - \Delta_f H°(AlO, 298.15\ K)] = 54\ kcal·mol^{-1}$, but these values have a large uncertainty. Gurvich *et al.*[6] selected EA(AlO) = 79.8 ± 2.4 kcal·mol^{-1} based on the equilibrium data.[1]

The value of $\Delta_r H°(AlO^- \rightarrow AlO + e^-, 298.15\ K)$ calculated from our tables will differ from a room temperature threshold energy due to inclusion of the enthalpies, $H°(0\ K) - H°(298.15\ K)$, of $AlO^-(g)$, AlO(g) and $e^-(g)$ and to the threshold effects discussed by Rosenstock *et al.*[7]

Heat Capacity and Entropy

All of the molecular constants are estimated by comparison with AlF and AlO.[3] We estimate the electronic states and levels from the low-lying states of isoelectronic AlF. The bond distance is taken equal to that in AlO and slightly shorter than that in AlF. B_e is calculated from r_e. We derive $\omega_e = 900 \pm 100\ cm^{-1}$ from k = 4.8 mdyn/Å estimated from k(AlF) = 4.23 and k(AlO) = 5.68. Similar comparisons of $\omega_e x_e/\omega_e$ and α_e/B_e are used to estimated $\omega_e x_e$ and α_e.

Gurvich *et al.*[6] calculated $C_p°$, $S°$ and $H°$ using somewhat larger estimates for ω_e and B_e. Their values of $S°$ differ from ours by −0.21 (298.15 K), −0.56 (2000 K) and −0.63 (4000 K) cal·K^{-1}·mol^{-1}.

Enthalpy of Formation

We adopt $\Delta_fH°(298.15\ K) = -20.6 \pm 8$ kcal·mol^{-1} and $\Delta_{at}H°(0\ K) = 216.52$ kcal·mol^{-1} derived from mass–spectrometric data measured by Ho and Burns[1] during laser evaporation of single crystals of Al_2O_3. $\Delta_fH°$ and $\Delta_{at}H°$ are consistent with limiting values from studies in two other laboratories that were unable to detect AlO_2^+.[2-3] AlO_2 appears to be much less stable than predicted by earlier data;[4-5] those differ from the adopted $\Delta_fH°$ by −19 to −23 kcal·mol^{-1}. Our analyses of the data are given below.

AlO_2 is the least abundant of the five Al–containing species identified in the vapor over Al_2O_3. Ho and Burns,[1] unlike Farber *et al.*,[4-5] identified AlO_2 as the source of the mass = 59 ion by accurate mass data combined with intensities and appearance potentials of AlO_2^+ and conceivable impurity ions. Their partial pressure[1] should be free of large error from mass = 59 ions other than AlO_2^+. Error does arise from *uncertainties in the evaporation coefficients, ionization cross sections and total flux of species.*[1] *An extreme example of this error is the* formation of α–Al_2O_3, which is biased by −9 kcal·mol^{-1} if calculated from the reported[1] pressures of Al and O. Our assigned uncertainty includes contributions from this error and that of the Gibbs–energy function.

Semiempirical calculations predicted $\Delta_fH°(298.15\ K) = -14.6$ and −24.3 kcal·mol^{-1} by the MNDO half–electron[6] and unrestricted Hartree–Fock[7] methods. These values agree with our adopted $\Delta_fH°$ but may be too uncertain to exclude the more negative value. Recent summaries[1,8] cite many other AlO_2 papers, including emission spectra and kinetic data that may not involve AlO_2. New studies[9] reassign much of the emission to an aluminum hydrate. We discount the bond–dissociation energies estimated from kinetics since formation of AlO_2 was inferred only from disappearance of AlO. Gurvich *et al.*[10] selected $\Delta_{at}H° = 215.1 \pm 7.2$ kcal·mol^{-1} based on different Gibbs–energy functions.

Heat Capacity and Entropy

We adopt a linear OAlO structure and estimate the bond length by correcting the predicted value[6] for OAlO using the bias[6,11] in predicted values for AlO and Al_2O. Electronic states are estimated from BO_2 and vibrational frequencies from several related molecules. The adopted frequencies correspond to $k_1 \approx 14.2$, $k_{12} \approx 0.5$ and $(k_8/l) \approx 0.086$ mdyn/Å. The Al–O stretching constant k_1 may be compared to 3.6 for Al_2O,[11] 4.0 for AlOH,[12] 5.5 for AlO[11] and 6.6 for FAlO.[12] We assume that $k_1/(k_8/l^2)49$ compared to 31 in BO_2 and 39 in FBO.

Linear OAlO is the most stable structure according to MNDO[6] and unrestricted Hartree–Fock[7] calculations. The latter predicts that linear A100 and cyclic AlO_2 are less stable by 22 and 38 kcal·mol^{-1}.[7] These predictions are not decisive but they are the best available. Spectral assignments are conflicting. IR bands in gas–plus–O_2 matrices have been assigned to each of three structures. A band at 523 cm^{-1} in neon was tentatively assigned[13] to OAlO, but comparison with GaO_2[14] suggests that it is more likely to be ν_2 of cyclic AlO_2. Assignments for ν_2 in argon include 496[15] and 717[16] cm^{-1}. Other assignments for cyclic AlO_2 include ν_1 = 1096[15] (Ar), 1177[16] (Ar), 1116[17] (Ar) and 1096[17] (N_2). and ν_3 = 525 cm^{-1},[16] (Ar). Assignments to A100 include 1336 and 1091 cm^{-1},[18] (N_2). Gurvich *et al.*[10] calculated functions for cyclic AlO_2 using 1096, 496 and 550 cm^{-1}; their values of the Gibbs energy function differ from ours by 1.4 and 0.2 J·K^{-1}·mol^{-1} at 298 and 2000 K.

Ground State Quantum Weight: [1] $\sigma = 2$
Point Group: [$D_{\infty h}$]
Bond Distance: Al–O = [1.68] Å
Bond Angle: O–Al–O = [180]°
Rotational Constant: B_0 = [0.186657] cm^{-1}

Enthalpy of Formation

We adopt the rounded value $\Delta_f H°(0\ K) = -115 \pm 12$ kcal·mol^{-1}, which corresponds to the electron affinity EA = 94.68 kcal·mol^{-1} for AlO_2.[1] This is based on equilibrium data[2-3] that yield [EA(AlO_2)–EA(Cl)] = 11.6 kcal·mol^{-1} and EA(AlO_2) = 94.9 kcal·mol^{-1}. Data for the reaction $AlO_2(g) + Cl^-(g) = AlO_2^-(g) + Cl(g)$ at 2080–2222 K were obtained by Srivastava, Uy and Farber[2-3] using effusion mass spectrometry. From their data we derive the values $\Delta_r H°(298.15\ K) = -11.7 \pm 0.9$ (3rd law) and -8.7 ± 8.6 (2nd law) kcal·mol^{-1} plus [$\Delta_r S°$(2nd law)–$\Delta_r S°$(3rd law)] = 1.4 ± 4.0 cal·K^{-1}·mol^{-1}). The third-law $\Delta_f H°$ yields $\Delta_f H°(AlO_2^-, g, 0\ K) = -115.2$ and EA(AlO_2) = 94.9 kcal·mol^{-1}. Gurvich *et al.*[9] selected $\Delta_f H°(0\ K) = -115.7 \pm 14.3$ and EA = 96.8 ± 12 kcal·mol^{-1} based on Srivastava *et al.*[2]

It is conceivable that this electron affinity is biased. New data show that similar studies of Farber *et al.* on $\Delta_a H°(AlO_2, g, 0\ K)$ may be biased by >20 kcal·mol^{-1}.[1] Two calculations[4-5] provide a test for bias in EA = $\Delta_r H°(AlO_2^- \rightarrow AlO_2 + e^-) = 94.9$ kcal·mol^{-1}. Vertical ionization potentials of 85.3 and 78.4 kcal·mol^{-1} were calculated for AlO_2^- by Gutsev and Boldyrev[4] using two different bases in the non–empirical discrete–variation Xα method. MNDO calculations of Davis *et al.*[5] gave 76.0 kcal·mol^{-1} instead of our adopted difference [$\Delta_f H°(AlO_2)$–$\Delta_f H°(AlO_2^-)$] = 96.3 kcal·mol^{-1} at 298.15 K. Although both calculations favor smaller values of EA, they may be too uncertain to yield a definite conclusion. New data are desirable for both AlO_2^- and AlO^-.[1]

The value of $\Delta_r H°(AlO_2^- \rightarrow AlO_2 + e^-, 298.15\ K)$ calculated from our tables will differ from a room temperature threshold energy due to inclusion of JANAF[1] enthalpies, $H°(0\ K)$–$H°(298.15\ K)$ of $AlO_2^-(g)$, $AlO_2(g)$ and $e^-(g)$ and to threshold effects discussed by Rosenstock *et al.*[6]

Heat Capacity and Entropy

We adopt a linear, symmetric structure and estimate the bond length to be 0.01 Å shorter than in AlO_2.[1] MNDO calculations[5] support this linear structure and also predict that the bond length of AlO_2^- is 0.007 Å shorter than in AlO_2. AlO_2^- is isoelectronic with SiO_2 and MgF_2, which are also believed to be linear.

We estimate the vibrational frequencies of AlO_2^-, together with those of AlO_2, from comparisons with SiO_2, OAlF, MgF_2, CO_2, OBF, BeF_2, BO_2^-, and BO_2. Our adopted values correspond to $k_1 \approx 5.6$, $k_{12} \approx 0.2$ and $(k_\delta/l^2) \approx 0.16$ mdyn/Å. The Al–O stretching constant k_1 may be compared to 5.5 in AlO,[1] 6.6 in OAlF and OAlCl[7] and 4.2 assumed in AlO_2.[1] We assume that $k_1/(k_\delta/l^2) \approx 35$. We take the ground state to be $^1\Sigma^+$ by analogy to other triatomics with 16 valence electrons.[8]

Gurvich *et al.*[9] calculated functions that differ by -1.3 cal·K^{-1}·mol^{-1} in entropy and Gibbs energy function.

Enthalpy of Formation

The adopted value of $\Delta_f H°(298.15\ K)$ is an average of 3rd law values from the equilibrium studies of Ficalora *et al.*[1] and Uy and Drowart.[2] Ficalora *et al.*[1] used mass spectrometric ion intensity data to study the equilibrium Al(g) + 1/2 S_2(g) AlS(g) and they reported 2nd and 3rd law values for $\Delta_f H°(298.15\ K)$ of -37.3 ± 3.0 kcal·mol^{-1} and -35.4 ± 2.0 kcal·mol^{-1}, respectively. Uy and Drowart[2] used mass spectrometric ion intensity data to study two different equilibria and report an average value of $D_0° = 88.4 \pm 1.9$ kcal·mol^{-1} via 3rd law techniques. Using auxiliary JANAF data[3] we calculate 3rd law values of $\Delta_f H°(298.15\ K) = 58.8 \pm 2.0$ kcal·mol^{-1} and $\Delta_f H°(298.15\ K) = 55.2 \pm 1.9$ kcal·mol^{-1} from the data of Ficalora *et al.*[1] and Uy Drowart[2] respectively. A complete reanalysis is impossible since neither set of authors report their raw data. Reanalysis is desirable since the free energy functions in this table differ from those in the older table[4] used by both sets of authors, due to inclusion of excited electronic states. A crude calculation shows that these differences are large enough to affect third-law results by as much as ±0.2 kcal·mol^{-1} which is within the uncertainty of the reported values. The adopted value of $\Delta_f H°(298.15\ K)$, coupled with auxiliary JANAF data,[3] yields an adopted $D_0° = 86.9 \pm 2.0$ kcal·mol^{-1}.

Heat Capacity and Entropy

With the exception of the two $^2\Pi$ states the adopted molecular constant data are from Huber and Herzberg[5] based on earlier absorption and emission spectroscopic studies by several authors. We have adopted a modified nomenclature system consistent with states for AlO,[3] but different from that of Huber and Herzberg for AlS.[5] This is desirable to accommodate the predicted low lying $^2\Pi_i$ state which is unobserved for AlS but has been observed for AlO. The energy of this $A^2\Pi$ state for AlS is predicted from relative energies of the two $^2\Pi$ states for AlO[3] and is consistent with INDO/S calculations[6] if the bias in these calculations for AlO is directly transferable to AlS. Molecular constant data for the $A^2\Pi$ state is predicted assuming the same relative differences between this state and the ground state as in AlO.

We adopt Lavendy's[7] molecular constant data for the $C^2\Pi$ state, except we use his experimental values of $B_0 = 0.2572$ cm^{-1} and $B_0 = 0.2495$ cm^{-1} for the 1/2 and 3/2 components in conjunction with the Pekeris relationship[8] to estimate values of B_e and α_e. Lavendy's emission spectroscopy measurements indicate that this state is highly perturbed and this is reflected in the unusually large differences between molecular constant data for the 1/2 and 3/2 components. The nature of the perturbing state was not identified. We treat the $C^2\Pi$ state as two separate electronic states separated by the spin–orbit coupling constant of 117.2 cm^{-1}. This approximation introduces little uncertainty since the entire $C^2\Pi$ state makes an entropy contribution of less than 0.1 cal·mol^{-1}·K^{-1} at 6000 K.

The largest uncertainty in the table is due to uncertainty in the estimated $A^2\Pi$ state. This state makes no contribution to the thermochemical functions below 500 K so its uncertainty is not reflected in that given for the $S°(298.15\ K)$ value. This state makes the following entropy contributions in cal·K^{-1}·mol^{-1}; 0.05 at 1000 K, 0.9 at 2000 K, 1.8 at 3000 K, 2.2 at 4000 K, 2.4 at 5000 K and 2.5 at 6000 K.

Enthalpy of Formation

From a mass–spectrometric investigation of the equilibria

$$AlAu(g) + Al(g) = Al_2(g) + Au(g)$$
$$2\ AlAu(g) = Al_2(g) + Au_2(g)$$

at 1921–2032 K and a 2nd law and 3rd law treatment of the data, Sterns and Kohl[1] derived the dissociation energy, $D_0° = 1.55 \pm 0.15$ eV for Al_2. Using current auxiliary data for $Al_2(g)$ and Al(g),[7] this value is corrected to 1.56 eV. As discussed by Stearns and Kohl,[1] it is likely that all of the previous mass spectrometic determinations[2, 3, 4] resulted in slightly high values for $D_0°$ (<1.96 ± 0.4 eV, 1.78 ± 0.19 eV and 1.80 eV, respectively) because of interferences due to the measurement of Al^+ ion intensities from extraneous sources. The dissociation energy of Al_2 has also been evaluated by a linear Birge–Sponer extrapolation[5] as 1.87 ± 0.2 eV and a graphical Birge–Sponer extrapolation[6] as 1.6 ± 0.2 eV. An ab initio calculation (LCAO–STO–MO–SCF–CI) by Leleyter and Joyes[9] yielded a dissociation energy of 1.03 eV. Based on the Stearns and Kohl result and auxiliary JANAF data,[7] we adopt $\Delta_f H°(298.15\ K) = 116.4 \pm 3.5$ kcal·mol for $Al_2(g)$.

Heat Capacity and Entropy

The bond spectrum of Al_2 was first reported by Zeeman[6] who wrongly attributed the emission to the AlC molecule. The vibrational constants are those reported by him. Values for the rotational constants are taken from Ginter *et al.*[5] who also assigned the upper and lower $^3\Sigma$ state configurations and energies. The electronic energies for the $^5\Sigma$ state and 1 $^3\Sigma$ state have been estimated by analogy with B_2. An ab initio SCF calculation of the ground state potential curve for Al_2^8 is reported but without inclusion of configuration interaction the calculated separations between states are not reliable.

PREVIOUS: June 1979 (1 atm) CURRENT: June 1979 (1 bar)

$S°(298.15\ K) = 66.29 \pm 0.13\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 2146 \pm 10\ K$

$\Delta_f H°(0\ K) = -2285.5 \pm 3.8\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -2300.78 \pm 3.8\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 170.008 \pm 3.8\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The adopted value of $\Delta_f H°(298.15\ K)$ is calculated from $\Delta_r H°(968\ K) = -4.0 \pm 0.3$ kcal·mol^{-1} for BeO(cr, α) + Al_2O_3(cr, α) → $BeAl_2O_4$(cr) using current values of $\Delta_f H°$ for the reactants.[1] The value of $\Delta_r H°(968\ K)$ was determined by Holm and Kleppa[2] from the difference in heats of solution of the three components in an oxide melt.

For comparison, a second-law treatment of the equilibrium data of Young[3] yields $\Delta_r H°(298.15\ K) = -2.3$ kcal·mol^{-1} for the same reaction. This is obtained from a suitable linear combination of the three equilibria studied by Young and leads to $\Delta_f H°(298.15\ K) = -548.2$ kcal·mol^{-1} in good agreement with the adopted value.

Heat Capacity and Entropy

Heat capacity and derived properties at and below 298.15 K are taken from the calorimetric data (16–380 K) of Furukawa and Saba.[4] The entropy is based on $S°(16\ K) = 0.004$ cal·K^{-1}·mol^{-1}. Above 298.15 K the adopted $C_p°$ are based on Ishihara and West's[5] merging of enthalpy data of Ditmar and Douglas[6] (323–1173 K) and Ishihara and West[5] (1182–2137) with the $C_p°$ data of Furukawa and Saba.[4] Values above 2137 K are our extrapolation. Ishihara and West report a sharp rise in enthalpy data above 2030 K, apparently associated with premelting phenomena. Data in this region was ignored by Ishihara and West during their treatment.

Fusion Data

Refer to the liquid table for details.

PREVIOUS: June 1972 CURRENT: December 1979

$S°(298.15\ K) = [126.406]\ J·K^{-1}·mol^{-1}$ $\Delta_f H°(298.15\ K) = [-2163.842]\ kJ·mol^{-1}$

$T_{fus} = 2146 \pm 10\ K$ $\Delta_{fus}H° = 170.008 \pm 3.8\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(BeAl_2O_4, l, 298.15\ K)$ is calculated from $\Delta_f H°(BeAl_2O_4, cr, 298.5\ K)$ by adding the enthalpy of fusion, $\Delta_{fus}H°$, and the difference in enthalpy, $H°(2146\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

Ishihara and West[2] reported enthalpy data from 2177 to 2355 K and reported a quadratic enthalpy equation for the liquid. This equation yields a temperature dependence for $C_p°$ which is unreasonably large. Therefore we have fit their enthalpy data to a linear equation which fits their measured points with an average deviation of 0.15 kcal·mol^{-1} and a maximum deviation of 0.35 kcal·mol^{-1}. Based on the scatter in the data we believe higher fits are unjustified and adopt the resulting constant value of $C_p° = 58.893\ cal·K^{-1}·mol^{-1}$ (246.408 J·K^{-1}·mol^{-1}) above the assumed glass transition at 1450 K. Below T_{gls}, $C_p°$ is taken to be the same as the crystal.

$S°(298.15\ K)$ is calculated in a manner analagous to that used for enthalpy of formation.

Fusion Data

The adopted melting point is taken from the phase study of Lang *et al.*[3] after adjustment to IPTS–68. We calculate $\Delta_{fus}H°$ from the difference between $H°(2146; 298.15)$ for the crystal[1] and liquid using our adopted linear enthalpy equation for the liquid.

Point Group: D_{2h}

Bond Distances: Al–Br = 2.222 ± 0.005 Å; Al–Br(bridge) = 2.414 ± 0.007 Å

Bond Angles: Br–Al–Br = 122.8 ± 3.3°; Br(bridge)–Al–Br(bridge) = 92.3 ± 0.9°

Product of the Moments of Inertia: $I_A I_B I_C = 8.865729 \times 10^{-110}\ g^3 \cdot cm^6$

Enthalpy of Formation

Vapor pressures over $AlBr_3$(cr) and $AlBr_3$(l) have been measured by Dunne and Gregory,[1] Fischer *et. al.*[2] and Sulzmann.[3] The vapor pressures were corrected for vapor non–ideality by means of the equation $\Delta G°/T = -R\ln P - BP/T$. The Bertholot equation of state and critical constants T_c=763 K and P_c=28.5 atm reported by Johnson, Silva and Cubicciotti[4] were used to calculate B. The corrected vapor pressures were used to calculate $\Delta_r H°(298.15\ K)$ by both 2nd and 3rd law methods. The results of the calculations are as follows with reaction (A) corresponding to 2 $AlBr_3$(cr)=Al_2Br_6(g) and reaction (B) corresponding to 2 $AlBr_3$(l)=Al_2Br_6(g).

[a]Point at 436.2 K rejected due to statistical test.

Heat Capacity and Entropy

Structural assignments for the dimer of aluminum tribromide are based on the electron diffraction data reported by Shen.[5] These values are in good agreement with earlier diffraction studies by Palmer and Elliott[6] and Akishin *et al.*[7] The principal moments of inertia are $I_A = 282.4212 \times 10^{-39}$, $I_B = 502.7859 \times 10^{-39}$ and $I_C = 624.3585 \times 10^{-39}\ g \cdot cm^2$. Beattie *et.al.*[8] measured the condensed phase IR and Raman bands for aluminum tribromide while Beattie and Horder[9] measured the gas phase Raman spectra. Perov *et al.*[10] investigated the IR spectra of monomeric and dimeric aluminum tribromide in a xenon matrix at 20–30 K. It has been established that the condensed phases of $AlBr_3$ are dimeric,[11,12] thus spectroscopic studies of the crystal and liquid pertain to the structure of Al_2Br_6(g). However, gas phase values are adopted in preference to condensed phase frequencies whenever possible. Five frequencies (ν_5, ν_6, ν_9, ν_{10}, ν_{15}) adjusted not only for consistency with the frequencies chosen for Al_2F_6(g) and Al_2Cl_6(g) but also for agreement between 2nd and 3rd law $\Delta_r H°(298.15\ K)$ values in the second data set tabulated above.

Enthalpy of Formation

The enthalpy of formation is calculated from the value for $AlCl_3$(cr) and the heat of sublimation as derived from vapor pressure data. Vapor pressures were corrected for vapor non-ideality by means of the equation $\Delta G°/T = -R \ln P - BP/T$. The Berthelot equation of state and critical constants T_c = 620 K[1] and P_c = 24.3 atm were used to calculate B. P_c is an extrapolation of the data given by Denisova and Baskova.[2] The corrected vapor pressures were used to derive $\Delta_{sub}H°(298.15\ K)$ by both 2nd law and 3rd law methods. The first nine data sets show good agreement between 2nd and 3rd law values and an average of $\Delta_{sub}H°(298.15\ K) = 27.61 \pm 0.55\ kcal \cdot mol^{-1}$ Al_2Cl_6 is adopted. The remaining data sets show serious discrepancies between 2nd and 3rd law values, indicating temperature dependent errors in measurement, and are given no weight.

*First number indicates number of data points used in calculation; number in parentheses indicates number of data points rejected.

Heat Capacity and Entropy

Structural assignments for the dimer of aluminum trichloride are based on the electron diffraction data reported by Shen.[11] These values are in good agreement with earlier electron diffraction studies by Palmer and Elliott[12] and Akishin *et al.*[13] and a theoretical investigation by Curtiss.[14] The principal moments of inertia are: $I_A = 108.2257 \times 10^{-39}$, $I_B = 206.7252 \times 10^{-39}$ and $I_C = 254.1948 \times 10^{-39}$ g cm^2. Klemperer[15] observed three frequencies in the infrared spectrum of Al_2Cl_6 vapor, Beattie and Horder[16] and Maroni *et al.*[17] reported gas phase Raman spectra, and Gerding and Smit[18] and Pershina and Raskin[19] measured liquid phase Raman frequencies. These earlier vibrational assignments were supplemented by matrix isolated/IR and Raman studies reported by Beattie et al[20] and Perov *et al.*[21] and the detailed vibrational analysis given by Tranquille and Fouassier.[22] Normal coordinate calculations have been reported by several investigators[23,24,17,25] but their basis on incomplete data makes many assignments doubtful. The new vibrational assignment incorporates the additional frequencies observed by Tranquille and Fouassier and differs with earlier calculations primarily in reassignment of the frequencies at 289 cm^{-1} and 161 cm^{-1}. The estimated fundamentals are based on comparisons with Al_2F_6, Al_2Br_6, and Al_2I_6 and are adjusted such that the entropy is consistent for the 2nd and 3rd law calculations above.

Potassium Aluminum Chloride ($K_3Al_2Cl_9$) CRYSTAL M_r = 490.33498

$\Delta_f H°$(0 K) = Unknown

$S°$(298.15 K) = [468.608] J·K^{-1}·mol^{-1} $\Delta_f H°$(298.15 K) = −2860 ± 12 kJ·mol^{-1}

T_{fus} = Unknown

Enthalpy of Formation

$\Delta_f H°(K_3Al_2Cl_9, cr, 298.15\ K)$ is calculated from the heat of solution, $\Delta_r H° = -112.07$ kcal·mol^{-1}, of $K_3Al_2Cl_9$(cr) in water (one mole of solute in 36 l. of water), as determined by Baud.[1]

Heat Capacity and Entropy

Heat capacities are estimated based on the assumption that the property of the mixed chloride ($2AlCl_3 + 3KCl$) is the sum of the corresponding values for its component chlorides, i.e. AlCl(cr) and KCl(cr). In a similar manner, $S°$(298.15 K) is estimated to be 112 cal·K^{-1}·mol^{-1}.

Enthalpy of Formation

The existence of small amounts of dimer in the saturated vapor was inferred from the intensities of AlF_2^+, AlF_3^+ and $Al_2F_5^+$ observed by mass spectrometry.[1,2,3] Buchler *et al.*[1] concluded that the precursor of the first two ions was mainly AlF_3, while the dimer was the precursor of $Al_2F_5^+$. Intensities of $Al_2F_5^+$ relative to those of AlF_2^+ were observed as 0.0057,[1] 0.007[2] and 0.025[3] at ionizing energies of 60, 90 and 100 V for vapor at 1025, 1100 and 1025 K, respectively.

The temperature dependence of ion intensities was used to derive 2nd law values of $\Delta_{sub}H°$ for monomer and dimer[1,2] and a value of $\Delta_{dim}H°$ based on an estimate for the $\Delta_{dim}S°$.[3] The absolute pressure of the monomer was obtained[2] from the relative ion intensity assuming a relative ionization cross section equal to two and neglecting other effects. Krause and Douglas[4] reported values for $\Delta_{sub}H°$(monomer), $\Delta_{dim}H°$, and $\Delta_{dim}S°$; these were derived by combination of $\Delta_{sub}H°$(dimer)[1] with precise sublimation pressures from entrainment data near 1200 K, where the dimer is more abundant. After reduction to 1000 K with JANAF functions, these results may be summarized as follows:

Source	Method	$\Delta_r H°$, kcal·mol^{-1}*			$\Delta_r S°$, cal·K^{-1}·mol^{-1}*		
		c → m	2c → d	2m → d	c → m	2c → d	2m → d
[4]	Entrainment	68.1 ± 0.4	[86]	−50 ± 3	[44.04]	—	−35 ± 3
[1]	Ion Intensities	67.3 ± 3	85.8 ± 3	−4.8 ± 3	—	—	—
[2]	Ion Intensities	70.5	92.1	−49.0	46.4	55.1	−37.7
[3]	Ion Intensities	—	—	−48.0 ± 4	—	—	[−32 ± 3]
JANAF	Adopted	68.4	87.8	[−49]	[44.37]	[52.83]	[−35.9]

*Reactions are abbreviated by c = crystal, d = dimer gas and m = monomer gas. Brackets enclose those values assumed in deriving the other values.

JANAF values are given in the last line. These are based on JANAF entropies, on $\Delta_{dim}H° = -49$ kcal·mol^{-1} for which there is close agreement, and on the entrainment pressures of Krause and Douglas.[4] Reduction of the dimer value to 298.15 K gives $\Delta_{sub}H° = 92.55 \pm 4$ and $\Delta_f H° = -629.45 \pm 4$ kcal·mol^{-1}. The table for AlF_3(g) gives a detailed comparison of observed and predicted total pressure along with predictions of the mole fraction of dimer in the saturated vapor. The latter are reasonably consistent with the relative ion intensities.

Heat Capacity and Entropy

The molecular structure is assumed to be similar to that of Al_2Cl_6. Bond distances and bond angles are estimated by comparison with AlF_3,[5] $AlCl_3$[5] and Al_2Cl_6.[5] The principal moments of inertia are $I_A = 35.3676 \times 10^{-39}$, $I_B = 79.7440 \times 10^{-39}$, $I_C = 94.6684 \times 10^{-39}$ g·cm^2.

Six observed vibrational frequencies are from infrared spectra of the dimer isolated in rare-gas matrices.[6] Unobserved fundamentals (2 in infrared, 9 in Raman and 1 inactive) are estimated such that the entropy is consistent with the result of Krause and Douglas[4] as given above. The estimated fundamentals are based on comparisons with Al_2Cl_6, Al_2Br_6 and Al_2I_6. Assignments used in the comparisons are minor modifications of those given by Beattie *et al.*[7]

Ground State Quantum Weight: [1] σ = 4

Point Group: D_{2h}

Bond Distances: Al–I = 2.449 ± 0.013 Å; Al–I (bridge) = 2.634 ± 0.03 Å

Bond Angles: I–Al–I = 115.0 ± 7.4°; I (bridge)–Al–I (bridge) = 99.6 ± 4.5°

Product of the Moments of Inertia: $I_A I_B I_C = 5.884591 \times 10^{-109}\ g^3\ cm^6$.

Enthalpy of Formation

The vapor pressure over $AlBr_3$(l) has been measured by Fischer, Rahlfs and Benze.[1] The vapor consists of both Al_2I_6(g) and AlI_3(g). Equilibrium constants for the reaction $Al_2I_6(g) = 2\ AlI_3(g)$ have also been determined by Fischer *et al.*[1] in the temperature range 614–843 K. From this data equilibrium constants at other temperatures were estimated and the partial pressures of Al_2I_6(g) over AlI_3(l) were calculated from the total pressure using these estimated values. The heats of reaction are calculated from the vaporization data using 2nd and 3rd law methods. The results of the calculations are as follows, where the $\Delta_f H°(298.15\ K)$ value is based on the 3rd law value of $\Delta_f H°(298.15\ K)$ and $\Delta_f H°(AlI_3, I, 298.15\ K) = -69.2\ kcal·mol^{-1}$.

Method	T/K	Data Points	$\Delta_f H°(298.15\ K)$, $kcal·mol^{-1}$ 2nd law	3rd law	Drift $cal·K^{-1}·mol^{-1}$	$\Delta_f H°(298.15\ K)$ $kcal·mol^{-1}$
Mass Loss	513.15–645.35	19[a]	21.50 ± 0.1	21.34 ± 0.0	−0.3 ± 0.1	−117.06

[a]One point at 493.95 rejected due to statistical test.
[b]One point at 482.95 rejected due to statistical test.

The adopted enthalpy of formation is $\Delta_f H°(Al_2I_6, g, 298.15\ K) = -117.0 \pm 2.0\ kcal·mol^{-1}$ (−489.528 ± 8.4 $kJ·mol^{-1}$)

Heat Capacity and Entropy

The molecular structure, bond distances and angles were obtained from the electron diffraction work of Shen.[2] These values are in good agreement with the earlier electron diffraction work by Akishin, Rambidi and Zasorin[3] and Palmer and Elliot.[4] The principal moments of inertia are $I_A = 530.1962 \times 10^{-39}$, $I_B = 963.2338 \times 10^{-39}$, and $I_C = 1152.2532 \times 10^{-39}\ g·cm^2$. Beattie, Gilson and Ozin[5] measured the condensed phase IR and Raman bonds for Al_2I_6 and Beattie and Horder[6] measured the gas phase Raman spectra. Five frequencies (ν_5, ν_6, ν_9, ν_{10}, ν_{15}) were adjusted not only for consistency with the frequencies chosen for Al_2F_6(g), Al_2Cl_6(g) and Al_2Br_6(g),[7] but also for agreement between 2nd and 3rd law $\Delta_f H°(298.15\ K)$ values in the data sets tabulated above.

$S°(298.15\ K) = 88.7 \pm 4.2\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 2048 \pm 20\ K$

$\Delta_f H°(0\ K) = -2283.07 \pm 1.3\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -2299.11 \pm 1.3\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = [192.464 \pm 21]\ kJ \cdot mol^{-1}$

Enthalpy of Formation

From differences in heats of solution of MgO(cr), Al_2O_3(cr, α) and $MgAl_2O_4$(cr) in a melt of $2PbOB_2O_3$ at 970 K, Charlu *et al.*,[1] derived $\Delta_f H°(970\ K) = -5.38 \pm 0.18\ kcal \cdot mol^{-1}$ for Al_2O_3(cr, α) + MgO(cr) → $MgAl_2O_4$(cr). When combined with auxiliary JANAF data,[2] this yields our adopted heat of formation. This value is within 3 $kcal \cdot mol^{-1}$ of earlier values determined via a similar method.[3,4] The direct measurement for formation from the elements, $\Delta_f H°(298.15\ K) = -567.1 \pm 0.3\ kcal \cdot mol^{-1}$, by Zaionchkovskii and Rubalskaya[5] appears to be widely discordant with other values.

Our 2nd and 3rd law analysis of all the equilibrium data is given below. Heats of formation based on the 3rd law analysis support the adopted heat of formation even though agreement between 2nd and 3rd law values is only fair. The two studies by Grojtheim *et al.* involving reaction 1 require significant activity corrections since the Al(l) is not pure as indicated but is alloyed with Mg[6] or Si.[8] Activities were obtained assuming the AlMg(l) solution is ideal as stated by the authors[6] and supported independently.[13] Activities used to correct the other study[8] are given by the authors in their paper.

Reactions:
(1) 4 MgO(cr) + 2 Al(l) → $MgAl_2O_4$(cr) + 3 Mg(g)
(2) 8 MgO(cr) + Al_4C_3(cr) → 2 $MgAl_2O_4$(cr) + 3 C(ref) + 6 Mg(g)
(3) 4 MgO(cr) + 3 AlCl(g) → $MgAl_2O_4$(cr) + $AlCl_3$(g) + 3 Mg(g)
(4) MgO(cr) + Al_2O_3(cr, α) → $MgAl_2O_4$(cr)

Heat Capacity and Entropy

The adopted low temperature $C_p°$ to 300 K is taken from the analysis of Douglas and Beckett[14] and based on the measurements of King[15] (54–296 K). The high temperature heat capacities are calculated from the equation given by Landa and Naumova[16] based on their enthalpy measurements (1500–2200 K) as well as those of Bonnickson[17] (421–1805 K). Enthalpies in the overlapping regions of these two studies agree within ±1%.

Integration of the low temperature heat capacity data leads to $S°(50\ K) = 0.299\ cal \cdot K^{-1} \cdot mol^{-1}$ and $S°(298.15\ K) = 19.268\ cal \cdot K^{-1} \cdot mol^{-1}$.[14] We assume that $S°(0\ K) = 1.93\ cal \cdot K^{-1} \cdot mol^{-1}$ to correct for the ~0.15 mole fraction of inverted cations present in synthetic samples of $MgAl_2O_4$; the method of calculation is given by Navrostsky and Kleppa.[18] This configurational entropy term cannot be determined from integration of the $C_p°$ data since the disorder remains at zero Kelvin.

Fusion Data

Refer to the liquid table for details.

Phase Data

This table refers to $MgAl_2O_4$ (spinel) with 15% inversion. Navrotsky and Kleppa[18] have discussed the thermodynamics of spinels in detail and the 15% inversion is typical of most synthetic spinels or of natural spinel after heating above ~1300 K. Natural spinel which has been annealed through geologic time may have the completely normal (ordered) structure. If so its entropy will be 1.93 $cal \cdot K^{-1} \cdot mol^{-1}$ less than in this table and its heat of formation will be ~0.9 $kcal \cdot mol^{-1}$ more exothermic than given here based on annealing–heat of solution experiments on natural spinel.[18] These measurements found the order–disorder transition to occur in the range 973–1300 K. There have been recent reports of second–order phase transitions in the 723–873 K range detected by X-ray[19] and thermal expansion studies[20] but these are not obvious in the enthalpy data given above.

Magnesium Aluminum Oxide ($MgAl_2O_4$) LIQUID M_r = 142.26568

$S°(298.15\ K)$ = [168.473] $J·K^{-1}·mol^{-1}$
T_{fus} = 2408 ± 20 K

$\Delta_f H°(298.15\ K)$ = [−2106.527] $kJ·mol^{-1}$
$\Delta_{fus}H°$ = [192.464 ± 21] $kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of formation of the liquid is calculated from that of the crystal by adding the enthalpy of $\Delta_{fus}H°$, and the difference in enthalpy, $H°(2408\ K)–H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The adopted $C_p°$ for the liquid is estimated to be 52.5 $cal·K^{-1}·mol^{-1}$ (219.66 $J·K^{-1}·mol^{-1}$) above an assumed glass transition at 1750 K. Below T_{gls}, the heat capacity is taken to be that of the crystal.[1] The heat capacity is estimated by assuming $C_p°$ = 7.5 $cal·K^{-1}·g·atom^{-1}$ as suggested by Kubaschewski and Alcock.[2]

$S°(298.15\ K)$ is calculated in manner similar to that used for the enthalpy of formation.

Fusion Data

Rankin and Merwin[3] studied the binary system alumina + magnesia and reported T_{fus} = 2408 ± 20 K for $MgAl_2O_4$(cr). Wilde and Rees[4] confirm this value in a later paper. The adopted heat of melting is 46 ± 5 $kcal·mol^{-1}$. This is estimated assuming that the entropy of melting per $g–atom^{-1}$ (2.7 $cal·K^{-1}$) is the same as that of Be_2O_4(cr).[1]

Bond Angle: Al–O–Al = 180° ± 10°
Rotational Constant: B_o = 0.104378 cm^{-1}

Enthalpy of Formation

We adopt the heat of atomization $\Delta_{at}H°$ = 250 ± 4 kcal·mol^{-1} and $\Delta_fH°$(298.15 K) = −34.7 ± 4 kcal·mol^{-1}. Six reactions analyzed below yield $D°$ values ranging from 247.4 to 252.7 kcal·mol^{-1}.[1–10] These values show no obvious dependence on the reaction and eight of the eleven fall in the range 250 ± 2 kcal·mol^{-1}. The overall uncertainty is about twice this range due to possible error in the data and the thermodynamic functions. The mass–spectrometric methods are uncertain due to use of several different approximations for ionization cross sections; some of these must be significantly in error. Other methods have their own uncertainties. We omit below two studies that were recently revised by Ho and Burns[1] and others, such as,[11] that we believe to be seriously biased.

Heat Capacity and Entropy

We adopt a linear Al–O–Al structure with a low bending frequency. The long–standing controversy over these properties has been greatly resolved by Douglas[12] who studied electronic absorption and emission spectra of Al_2O in Kr and Ar matrices. Vibrational progressions in the spectra[12] gave 471 ± 15, ~482 and ~452 cm^{-1} for ν_1 of the X, A and C states, respectively, plus ~133 and ~170 cm^{-1} for ν_2 of the A and C states. This supplements previous evidence of linearity, i.e. absence of υ_1 in IR spectra[13–18] absence of deflection by an inhomogenous electric field[19] and theoretical predictions.[20] IR spectra[13–18] also failed to show ν_2, which has been estimated as 102 or 120 ± 30 cm^{-1} from SCF calculations[20] or force constants.[17] The evidence suggests that the X state has $\nu_2 \leq$ 170 cm^{-1} implying that the equilibrium bond angle[21] is much closer to 180° than the uncorrected angle of 141° derived from electron diffraction. Likewise, the angle of 140°–150°[15] derived from the isotopic shift of ν_3 becomes nearly 180°[12] if corrected for anharmonicity.

We conclude that the bond angle is 180° ± 10° and adopt the bond distance from electron diffraction.[21] Frequencies ν_1 and ν_3 are from[12] and,[13–18] while ν_2 = 160 cm^{-1} is chosen to reproduce the entropy derived from equilibria (see δS in the table above). Electronic levels are from;[12] states A and C probably are bent. The band found[18] at ~24400 cm^{-1} is from Al_2.[12] Values of Gibbs energy function from Gurvich *et al.*[22] are 1.0 cal·K^{-1}·mol^{-1} larger than ours at T>1400 K.

Ground State Quantum Weight: [2] $\sigma = 2$
Point Group: [$D_{\infty h}$]
Bond Distance: Al–O = [1.73] Å
Bond Angle: Al–O–Al = [180]°
Rotational Constant: B_0 = [0.104379] cm^{-1}

Enthalpy of Formation

$\Delta_f H°(Al_2O^+, g, 0\ K)$ is calculated from that of Al_2O[1] using Hildenbrand's appearance potential[2] of 8.20 ± 0.15 eV (189.1 ± 3.5 $kcal·mol^{-1}$. We assume that the appearance potential is identical with the ionization potential for $Al_2O(g) \rightarrow Al_2O^+(g) + e^-(g)$. Other values reported for the appearance potential include 7.7 ± 0.5,[3,4] 7.9 ± 0.3,[5] 8.0 ± 0.5,[6] 8.5 ± 0.5[7] and 8.5 ± 0.2 eV.[8] These values are consistent with, but less precise than, the adopted value.

$\Delta_f H°(298.15\ K)$ is obtained from $\Delta_f H°(Al_2O)$ by using IP(Al_2O) with JANAF[1] enthalpies, $H°(0\ K)–H°(298.15\ K)$, for $Al_2O(g)$, $Al_2O^+(g)$ and e^- (g). $\Delta_f H°(Al_2O \rightarrow Al_2O^+ + e^-, 298.15\ K)$ differs from a room–temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[9] $\Delta_f H°(298.15\ K)$ should be changed by −1.481 $kcal·mol^{-1}$ if it is to be used in the ion convention that excludes the enthalpy of the electron. MNDO calculations[10] differ by only −9.9 $kcal·mol^{-1}$ from our value of [$\Delta_f H°(Al_2O^+, 298.15\ K) - \Delta_f H°(Al_2O, 298.15\ K)$] even though the MNDO values of $\Delta_f H°(298.15\ K)$ differ by −47 and −37 $kcal·mol^{-1}$.

Heat Capacity and Entropy

Al_2O^+ is assumed to be linear as predicted by MNDO calculations[10] and by the correlation of Walsh.[11] We assume that the bond distance is the same as that in Al_2O[1] since the change in bond length on ionization was predicted to be only 0.004 Å.[10] Vibrational frequencies are estimated to be somewhat lower than those of Al_2O since the ion has one less bonding electron. The electronic ground state is doublet due to the odd number of electrons.

Enthalpy of Formation

We adopt $\Delta_fH°$(298.15 K) = −94.3 ± 8 and $\Delta_{at}H°$ = 368 ± 8 kcal·mol^{-1} based on the mass-spectrometric studies summarized below. Data of Chervonnyi[2] and Drowart[4] are analyzed using the isomolecular reaction B instead of the atomization reaction A, which is much affected by probable bias in calibrations and relative ionization cross sections. Reaction A would give discrepancies of −16 to +5 kcal·mol^{-1} in $\Delta_{at}H°$. Use of reaction B emphasizes the consistency among the studies. Only the result of Farber *et al.*[3] appears to be discrepant. JANAF auxiliary data[5] have been used to calculate the $\Delta_fH°$ values; their uncertainties include a large contribution from possible bias in the Gibbs-energy function. Gurvich *et al.*[6] selected $\Delta_fH°$(298.15 K) = −96.96 and $\Delta_{at}H°$ = 370.5 ± 12 kcal·mol^{-1} based on somewhat different functions and without benefit of the data of Ho.[1]

[a]Reactions: A) 2 Al(g) + 2 O(g) = Al_2O_2(g); B) Al_2O(g) + AlO(g) = Al(g) + Al_2O_2(g).

[b]Reaction B used instead of A to minimize bias from calibrations and ionization cross sections.

[c]Temperature scale adjusted to T = 2327 K instead of 2318 K for α–Al_2O_3.

[d]Ho and Burn's recalculations[1] ofthe results of Fu[1] and Drowart[4] yield $\Delta_{at}H°$ = 367.0[1] and −364.6[4] kcal·mol^{-1} when converted to our new Al_2O_2 functions.

[e]Tungsten cell.

[f]Molybdenum cell.

Heat Capacity and Entropy

We adopt a square–planar structure of D_{2h} symmetry. The Al–O bond distance is taken as 1.8 Å, i.e., 0.1 Å longer than the predictions of ab initio[7] and MNDO[8] calculations and 0.07 Å longer than observed in Al_2O.[5] Similar predictions for Al_2O are I_A = 8.6080 × 10^{-39}, I_B = 14.5167 × 10^{-39} and I_C = 23.1247 × 10^{-39} g·cm^2.

Vibrational frequencies are estimated to be lower than values from MNDO calculations[8] but higher than Al_2F_2 values from ionic model calculations.[10] Matrix IR spectra gave a band near 496 cm^{-1} that was assigned to D_{2h} Al_2O_2 in three studies[11] but to cyclic AlO_2 in another.[12] A band at 686 cm^{-1}, once assigned to Al_2O_2,[13] was reassigned to $Al(O_2)_2$ by Finn[11] who also attributed bands at 490 and −1215 cm^{-1} to a C_{2v} form of Al_2O_2.

Evidence is contradictory on the most stable geometry. The square–planar form is 15 kcal·mol^{-1} more stable than linear AlOAlO according to ab initio calculations[7] but 27 kcal·mol^{-1} less stable according to MNDO calculations.[8-9] Also possible is rhombic D_{2h} AlO_2Al with an O–O bond similar to that predicted by ab initio methods for LiO_2Li.[14] This geometry was not considered in the ab initio study[7] and showed no minimum in the MNDO study.[8] Better calculations are needed to resolve the question. Thermochemical and spectral evidence is inconclusive.[15] Uncertainties in the structure and vibrational frequencies cause an uncertainty of ≤3 cal·K^{-1}·mol^{-1} in $S°$ and $-(G°-H°)/T$ at 2000 K. Estimated values for the rhombic peroxide[6] are ~1 cal·K^{-1}·mol^{-1} lower at 2000 K but this difference could be plausibly reversed by use of lower frequencies.

Ground State Quantum Weight: [2] σ = [4]
Point Group: [D_{2h}]
Bond Distance: Al–O = [1.80] Å
Bond Angles: O–Al–O = [90]°; Al–O–Al = [90]°
Product of the Moments of Inertia: $I_A I_B I_C$=[2.889607 × 10^{-114}] $g^3·cm^6$

Enthalpy of Formation

$\Delta_f H°$(0 K) is calculated from that of Al_2O_2[1] using the appearance potential 9.9 ± 0.5 eV.[2-3] We assume that the appearance potential is equal to the ionization potential for $Al_2O_2(g) \rightarrow Al_2O_2(g) + e^-(g)$. Other reported appearance potentials include 10 ± 1[4-5] and 10 eV.[6]

$\Delta_f H°$(298.15 K) is obtained from $\Delta_f H°(Al_2O_2, 0\ K)$ by using IP(Al_2O_2) with JANAF[1] enthalpies $H°(0\ K)-H°(298.15\ K)$ for Al_2O_2(g), Al_2O_2 (g) and e (g). $\Delta_r H°(Al_2O_2 \rightarrow Al_2O_2^+ + e^-, 298.15\ K)$ differs from a room-temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[7] $\Delta_f H°$(298.15 K) should be changed by −1.481 $kcal·mol^{-1}$ if it is to be used in the convention that excludes the enthalpy of the electron. MNDO calculations[8] predicted $\Delta_f H°(Al_2O_2^+, 298.15\ K)$ = 78.7 and $[\Delta_f H°(Al_2O_2^+, 298.15\ K) - \Delta_f H°(Al_2O_2, 298.15\ K)]$ = 186.7 $kcal·mol^{-1}$ for the linear Al–O–Al–O ion and neutral molecule; our adopted values are larger by 43 and 57 $kcal·mol^{-1}$, respectively.

Heat Capacity and Entropy

The structure of $Al_2O_2^+$ is probably even more uncertain than that of Al_2O_2.[1] MNDO calculations[8] predict an Al–O–Al–O ion that is essentially linear, but a similar prediction for the neutral molecule is contradicted by ab initio calculations.[1] Pending resolution of this discrepancy, we arbitrarily adopt a square-planar structure like that adopted for Al_2O_2.[1] We assume the same bond distance as in Al_2O_2 since the changes on ionization are predicted to be small.[8] Vibrational frequencies are estimated to be slightly lower than those of Al_2O_2.[1] We assume the ground electronic state to be doublet, due to the odd number of electrons, and neglect excited states. The principal moments of inertia are: I_A = 8.6079 × 10^{-39}, I_B = 14.5167 × 10^{-39} and I_C = 23.1246 × 10^{-39} $g·cm^2$.

PREVIOUS: December 1979 (1 atm) CURRENT: December 1979 (1 bar)

$S°(298.15\ K) = 50.950 \pm 0.08\ J\cdot K^{-1}\cdot mol^{-1}$
$T_{fus} = 2327 \pm 6\ K$

$\Delta_f H°(0\ K) = -1663.6 \pm 1.2\ kJ\cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1675.7 \pm 1.2\ kJ\cdot mol^{-1}$
$\Delta_{fus} H° = 111.1 \pm 4\ kJ\cdot mol^{-1}$

Enthalpy of Formation

The adopted $\Delta_f H°$ is from calorimetric heats of combustion measured by Mah[1] and Holley and Huber.[2] Early measurements of the heat of combustion of Al were seriously biased,[3] but the sources of bias were minimized in later studies. After conversion to the present atomic weight of Al these studies yield $\Delta_f H°$ values of -400.5 ± 0.25,[1] -400.5 ± 0.3,[2] -399.2 ± 0.3,[3] and -402 ± 2 or -400.6 ± 1.4[4] $kcal\cdot mol^{-1}$.

$\Delta_f H°$ is the value adopted by CODATA.[5] This direct calorimetric result has been criticized by various authors who proposed less negative $\Delta_f H°$ values, for example -393[6] and -397.1[7] $kcal\cdot mol^{-1}$ based on emf and mineralogical data, respectively. Plausible explanations have been suggested[8,9] for these different values. Moreover, the adopted $\Delta_f H°$ is confirmed by several direct and indirect measurements.

New direct confirmation includes $\Delta_f H° = -400.2 \pm 0.4$ *and* $\Delta_f H° < -399.9\ kcal\cdot mol^{-1}$ *obtained, respectively, from emf measurements*[10] of $\Delta_f G°(1030–1250\ K)$ and from heat of combustion.[11] Indirect confirmation comes from data on reactions that link $\alpha-Al_2O_3$ to other aluminum compounds. K_p data[12,13] at high temperature yield $\Delta_f H° = -401.9 \pm 1.5\ kcal\cdot mol^{-1}$ from $AlCl_3(g)$ and -405.2 ± 1.5 from $AlF_3(cr)$, although the latter value may be biased if aluminum oxyfluorides[14] were formed. $\Delta_f H°$ is confirmed to within 1.0 $kcal\cdot mol^{-1}$ by equilibria and calorimetry for independent reaction cycles involving each of the minerals mullite,[11] kaolinite[9] and gibbsite.[15] Data on many related minerals have been carefully evaluated by Haas *et al.*,[16] they found no inconsistency large enough to require a change in $\Delta_f H°$ of Al_2O_3.

Heat Capacity and Entropy

$C_p°$ is from the equations of Ditmars *et al.*[17,19] for NBS Standard Reference Material 720 ($\alpha-Al_2O_3$). These equations are based on NBS data: $C_p°$ of Chang[18] (8.6 to 371 K) and enthalpy data of Ditmars and Douglas[19] (323 to 1173 K) and Ditmars *et al.*[17] (1173 to 2257 K). We increase $C_p°$ slightly (by <0.2%) above 1700 K to avoid a rapidly rising extrapolation above T_{fus}. $C_p°$ from the equation[17,19] has an upward inflection point near 2050 K that is not necessarily justified by the data.[17]

$S°(298.15\ K) = 12.177 \pm 0.02\ cal\cdot K^{-1}\cdot mol^{-1}$ is obtained from $C_p°$ based on $S°(9\ K) = 0.00053\ cal\cdot K^{-1}\cdot mol^{-1}$. CODATA[5] and Gurvich *et al.*[20] selected the slightly smaller values $S° = 12.17 \pm 0.02\ cal\cdot K^{-1}\cdot mol^{-1}$ and $H°(298.15\ K)–H°(0\ K) = 2.394 \pm 0.005\ kcal\cdot mol^{-1}$. We choose instead to be consistent with newly certified values for SRM 720.

Fusion Data and Sublimation Data

PREVIOUS: June 1975 CURRENT: December 1979

$S°(298.15\ K)$ = [50.6 ± 4] $J·K^{-1}·mol^{-1}$
T_{fus} = [2308] K

$\Delta_f H°(0\ K)$ = [−1653.9 ± 4] $kJ·mol^{-1}$
$\Delta_f H°(298.15\ K)$ = −1666.5 ± 4 $kJ·mol^{-1}$
$\Delta_{fus} H°$ = [93.3] $kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is calculated from that of α–Al_2O_3[1] using $\Delta_f H°(978\ K)$ = −2.7 ± 0.4 $kcal·mol^{-1}$ for the irreversible process $\delta \rightarrow \alpha$. This yields $\Delta_f H°(298.15\ K)$ = −2.2 $kcal·mol^{-1}$ based on our adopted functions. Yokokawa and Kleppa[2] determined $\Delta_f H°$ for the two crystalline forms from the difference in their heats of solution in an oxide melt at 978 K. DTA studies by Gani and McPherson[3] gave $\Delta_f H°$ = −2.8 ± 0.5 $kcal·mol^{-1}$. Assuming T = −1400 K, we derive $\Delta_f H°(298.15\ K)$ = −1.9 $kcal·mol^{-1}$. This confirms the calometric result. Both samples of δ–Al_2O_3 had been obtained by rapid quenching from high temperature, one[2] from combustion of Al_4C_3 and the other[3] by a plasma method.

Heat Capacity and Entropy

$C_p°$ is assumed to be 3% larger than that of α–Al_2O_3[1] by comparison with the observed values for κ–Al_2O_3[1] and the adopted values for γ–Al_2O_3.[1] $S°$ is selected such that $\Delta_r G°(\kappa \rightarrow \delta) < 0$ below T_{fus} and $\Delta_r G°(\delta \rightarrow \alpha) < 0$ at $T \leq 2400$ K.

Marchidan *et al.*[4] measured enthalpy data (573–1177 K) for a sample designated only as TA–600 alumina. They attributed a transition at ~993 K (720°C) to the irreversible process $\eta \rightarrow \delta$. This temperature corresponds roughly to processes designated as either (γ or η) $\rightarrow \theta$ or $\gamma \rightarrow \delta$ by Lippens and Steggerda.[5] DTA data of Alevra *et al.*[6] showed an endotherm near 750 °C subsequent to the dehydration of hydroxide samples; however, TGA data indicated that the resulting alumina still retained considerable water at this temperature. The enthalpy data,[4] (1003–1177 K) are 4.7 ± 0.3% larger than those of α–Al_2O_3[1] and presumably correspond to an alumina containing a significant amount of water. The δ–Al_2O_3 used in $\Delta_f H°$ studies was presumably essentially anhydrous. Thus, we omit the enthalpy data[4] on the presumption that they are larger than those of our standard state which is anhydrous δ–Al_2O_3.

Phase Data

The stable crystalline form is corundum (α–alumina). Δ–alumina is one of several structurally related, metastable forms. These occur in "active alumina" and are much studied[5] due to their importance in adsorbents and catalysts. Lippens and Steggerda[5] summarized the classifications of metastable forms, their crystal stuctures and conditions of formaiton by dehydration. Mixtures of the closely related δ– and θ–aluminas are also formed by rapid cooling of droplets of molten alumina following their passage through a flame.[7] There is some controversy[5] over the X–ray data and unit–cell dimensions of δ–Al_2O_3 formed by the two methods. Recent data[8] for θ–Al_2O_3[5] suggest a similar controversy. Δ–alumina belongs to the "nearly anhydrous", high–temperature classification[5] based on the temperature of 600° to 900°C at which it forms during dehydration. The irreversible transitions $\delta \rightarrow \theta(+\alpha) \rightarrow \alpha$ are thermally activated at tempertures of 800°–1050 °C for the first step[5,6] and −1200 °C for the final step.[5]

Fusion Data

The hypothetical melting point of metastable δ–phase is calculated as the temperature at which $\Delta_r G°(\delta \rightarrow l) = 0$. $\Delta_{fus} H°$ is the corresponding difference in $\Delta_f H°$.

PREVIOUS: June 1975 CURRENT: December 1979

$S°(298.15\ K) = [52.3 \pm 8]\ J\cdot K^{-1}\cdot mol^{-1}$
$T_{fus} = [2289]\ K$

$\Delta_f H°(0\ K) = [-1644.3 \pm 6.3]\ kJ\cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1656.9 \pm 6.3\ kJ\cdot mol^{-1}$
$\Delta_{fus} H° = [78.49]\ kJ\cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is calculated from that of $\alpha-Al_2O_3$[1] using $\Delta_f H°(978\ K) = -5.3\ kcal\cdot mol^{-1}$ for the irreversible process $\gamma \rightarrow \alpha$. Yokokawa and Kleppa[2] determined $\Delta_f H°$ for the two crystalline forms from the difference in their heats of solution in an oxide melt at 978 K. This yields $\Delta_f H°(298.15\ K) = -4.5\ kcal\cdot mol^{-1}$ based on our adopted functions. DTA studies by Gani and McPherson[3] gave $\Delta_f H°(\gamma \rightarrow \alpha) = -5.8 \pm 1.6\ kcal\cdot mol^{-1}$. Assuming $T = -1400$ K, we derive $\Delta_f H°(298.15\ K) = -4.4\ kcal\cdot mol^{-1}$ which confirms the calorimetric result.[2] Yamada *et al.*[4] used dynamic, adiabatic calorimetry to measure $\Delta_f H°(773\ K) = 12.6 \pm 1.1\ kcal\cdot mol^{-1}$ for $Al_2O_3H_2O$(cr, boehmite) $\rightarrow Al_2O_3(\gamma) + H_2O(g)$. Enthalpies from[4,1] convert this to $\Delta_f H°(298.15\ K) = 17.54 \pm 1.3\ kcal\cdot mol^{-1}$, yielding $\Delta_f H°(\gamma-Al_2O_3, 298.15\ K) = -398.1 \pm 1.5$ or $-396.7 \pm 2\ kcal\cdot mol^{-1}$ based on new or old values for $\Delta_f H°$(boehmite, 298.15 K)) $= -473.4 \pm 0.4$[5] or -472.0[6] $kcal\cdot mol^{-1}$.

We adopt $\Delta_f H°(\gamma, 298.15\ K) = -396.0 \pm 1.5\ kcal\cdot mol^{-1}$ and $\Delta_f H°(\gamma \rightarrow \alpha, 298.15\ K) = -4.5\ kcal\cdot mol^{-1}$. These values derive[2] from the highest ignition temperature prior to the appearance of a more stable phase ($\kappa-$ or $\alpha-Al_2O_3$) in the sample. This standard state should involve maximum attainable crystal development and minimum residual water. γ-alumina shows much variability depending on its thermal history. Lower ignition temperatures gave values of $\Delta_f H°(\gamma \rightarrow \alpha)$ more negative by as much as 2.5 $kcal\cdot mol^{-1}$.[1,2] Other reported values of $\Delta_f H°(\gamma \rightarrow \alpha)$, including -4.5 to -7.5,[3] -7.7,[7] -9.1,[8] -11.0[9] and -7.8[10] $kcal\cdot mol^{-1}$, tend to be skewed toward more negative values. These values correspond to less stable samples, presumably with more residual water and less well developed crystal structure. This is consistent with $\Delta_f H°(298.15\ K) = -388 \pm 2\ kcal\cdot mol^{-1}$ observed[4] for $\rho'-Al_2O_3$ which is nearly amorphous.

Heat Capacity and Entropy

$C_p°$ is assumed to be 4.7% larger than that of $\alpha-Al_2O_3$.[1] Structural and related characteristics[11] suggest that $C_p°(\gamma) > C_p°(\kappa)$ which in turn is ~2.2% larger[1,4] than $C_p°(\alpha)$. Our estimate is derived from Marchidan *et al.*[12] who measured enthalpies (1003–1177 K) which are $4.7 \pm 0.3\%$ larger than those of $\alpha-Al_2O_3$. $S°$ is estimated such that $\Delta_f G°(\gamma \rightarrow \alpha) < 0$ at $T \leq 2400$ K. This is consistent with observed stability relationships.[11,2]

Marchidan *et al.*[12] measured enthalpy data (573–1177 K) for a sample designated only as TA–600 alumina. They attributed a transition at -993 K to the irreversible process $\eta \rightarrow \delta$. Comtemporary studies[13] from the same institution lead us to presume that the TA–600 sample retained a significant amount of water even above the transition. The "low–temperature" forms γ and η are difficult to distinquish;[11] they retain more water[11,13] than the "high–temperature" forms. This may explain the unusual enthalpy data attributed[12] to $\eta-Al_2O_3$; these deviate from $\alpha-Al_2O_3$ by + 12.4% at 573 to 620 K and then decrease linearly to +3.8% at 991 K. These data do not seem suitable for standard–state $\gamma-Al_2O_3$ having minimum water content and maximum crystal development. We adopt instead the constant deviation of +4.7% found at higher temperature. Differential enthalpy analysis[8] gave an enthalpy 2% larger than $\alpha-Al_2O_3$ at 1290 K, but the error is large (±4% in enthalpy) and no information is given on the sample history. The observed $\Delta_f H(\gamma \rightarrow \alpha) = -9.1\ kcal\cdot mol^{-1}$ [8] suggests the sample differed from our desired standard state.

The adopted entropy may be compared with the value $\Delta S°(\alpha \rightarrow \gamma) = 1.56\ cal\cdot K^{-1}\cdot mol^{-1}$ estimated by Borer and Gunthard[14] for the "defect" spinel structure of $\gamma-Al_2O_3$. This yields $S°(\gamma, 298.15\ K)) = 13.7$ or 14.3 $cal\cdot K^{-1}\cdot mol^{-1}$ assuming $C_p°(\gamma)/C_p°(\alpha) = 1.00$ or 1.047, respectively. The authors' assumption[14] concerning the structure of $\gamma-Al_2O_3$[11] is overly simplified.

Phase Data

The stable crystalline form is corundum (α–alumina). γ–alumina is one of several structurally related, metastable forms. These occur in "*active alumina*" *and are much studied*[11] *due to their importance in adsorbents and catalysts. Lippens and Steggerda*[11] *summarized the* classifications of metastable forms, their crystal structures and conditions of formation by dehydration. "Low–temperature" forms γ and η have similar X–ray diffraction patterns. Their nomenclature is confused in the literature. The term $\gamma-Al_2O_3$ has been applied to either form and as a generic term for all low temperature forms. γ and η are often poorly crystallized and difficult to distinquish.[11] They retain various amounts of water[11,13] depending on their thermal history. The low–temperature forms are obtained by dehydrating temperatures not exceeding 600 °C and change irreversibly to "high–temperature" forms (δ, θ or κ) at 600° to 900 °C.[11,13,2]

Fusion Data

The hypothetical melting point of metastable γ–phase is calculated as the temperature at which $\Delta_f G°(\gamma \rightarrow l) = 0$. $\Delta_{fus} H°$ is the corresponding difference in $\Delta_f H°$.

PREVIOUS: June 1975 CURRENT: December 1979

$S°(298.15\ K) = [53.6 \pm 4]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = [2312]\ K$

$\Delta_f H°(0\ K) = [-1650.0 \pm 4]\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1662.3 \pm 4\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = [91.2]\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is calculated from that of α–Al_2O_3[1] using $\Delta_f H°(978\ K) = -3.6\ kcal \cdot mol^{-1}$ for the irreversible process κ → α. This yields $\Delta_f H°(298.15\ K) = -3.2\ kcal \cdot mol^{-1}$ based on our adopted functions. Yokokawa and Kleppa[2] determined $\Delta_f H°$ for the two crystalline forms from the difference in their heats of solution in an oxide melt at 978 K. Yamada *et al.*[3] derived $\Delta_f H°(298.15\ K) = -397 \pm 1\ kcal \cdot mol^{-1}$ from the same data.

Heat Capacity and Entropy

$C_p°$ (380 to 1110 K) was measured by Takahashi *et al.*[4] using a dynamic, adiabatic calorimeter with an open–type container for the sample. Reproducibility of the data was reported to be within ±1.5% up to 1100 K. We represent the observed data by a $C_p°$ curve which is 2.2% larger than that of α–Al_2O_3.[1] Deviations from the adopted curve exceed 1.0% for only 3 of the 39 points:[4] i.e., −1.6% (400 K), +1.4% (993.8 K) and +1.3% (1070.8 K). Takahashi *et al.*[4] prepared their κ–Al_2O_3 by dehydration of tohdite ($Al_2O_3$1/5 H_2O) at 840 °C under a vacuum of 10^{-5} torr.

$S°$ is selected arbitrarily so that $\Delta_r G°(\kappa \rightarrow \alpha) = 0$ near 2400 K. This is consistent with the view that κ–phase is unstable with respect to α–phase at all temperatures below T_{fus}.

Phase Data

The stable crystalline form is corundum (α–alumina). Kappa–alumina is one of several structurally related, metastable forms. These occur in "active alumina" and are much studied[5] due to their importance in adsorbents and catalysts. Lippens and Steggerda[5] summarized the classifications of metastable forms, their crystal structures and conditions of formation by dehydration. Okumiya *et al.*[6] recently published an extensive study on the formation and structural relations of κ–Al_2O_3 and its precursors κ'–Al_2O_3 and tohdite. κ–alumina belongs to the "nearly anhydrous", high–temperature classification[5] based on its formation temperture of 900° to 1000 °C (somewhat lower in vacuo). The irreversible transition κ → α is thermally activated at −1200 °C.[2,5] Thermochemical studies cited in this table presume that the samples of κ–Al_2O_3 were essentially anhydrous.

Fusion Data

The hypothetical melting point of metastable κ–phase is calculated as the temperature at which $\Delta_r G°(\kappa \rightarrow l) = 0$. $\Delta_{fus} H°$ is the corresponding difference in $\Delta_f H°$.

PREVIOUS: June 1975 CURRENT: December 1979

$S°(298.15\ K) = [67.298]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 2327 \pm 6\ K$

$\Delta_f H°(298.15\ K) = [-1620.567]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 111.1 \pm 4.2\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is calculated from that of the crystal by adding the enthalpy of fusion and the difference in enthalpy, $H°(2327\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

Enthalpy data for the liquid include those of Shpil'rain *et al.*,[1,2] (2326 to 3104 K), Sheindlin *et al.*,[3] (2350 to 2800 K), Kantor *et al.*[4,5] (2337 to 2480 K), and approximate values of West and Ishihara[6] (2345 to 2495 K). The latest study[1,2] is the most extensive. It satisfactorily resolves the discrepancy in $C_p°$ which was reported earlier to be 47.7[3] or 34.6[4] $cal·K^{-1}·mol^{-1}$. The new data[1,2] yield 46.0 $cal·K^{-1}·mol^{-1}$, assuming $C_p°$ is independent of temperature. Although Shpil'rain *et al.*[1,2] derived a $C_p°$ which decreases linearly with increasing temperature, this does not significantly improve the fit of the enthalpy data. The apparent value of the temperature coefficient of $C_p°$ is very data dependent; it changes sign on omission of the point at 2326 K (2323 K, IPTS-48).

We adopt $C_p° = 46.0\ cal·K^{-1}·mol^{-1}$. Compared to our adopted functions, the enthalpy data deviate by $< \pm 1.0\%$,[1,2] −0.9 to −0.1%.[3] (equation), +2.4 to +0.2%[4,5] and +2 to +5%.[6] We assume a glass transition at 1350 K, below which $C_p°$ is taken to be the same as for Al_2O_3(cr, α). The entropy is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

$T_{fus} = 2054 \pm 6°C$ was recommended by Schneider[7] as the result of a cooperative measurement of the melting point by nine groups in seven countries. We adopt this value. It is confirmed by several recent studies (e.g.8–10); however, Nelson *et al.*[11] suggested the possibility that T_{fus} may be somewhat different in an oxygen atmosphere than in inert gases or vacuum.

$\Delta_{fus} H°$ is the difference at T_{fus} between the adopted enthalpy fits of Al_2O_3(l) and Al_2O_3(α). Reported calorimetric values of $\Delta_{fus} H°$ include 25.7 ± 1.3,[1,2] 25.9,[3] and 28.3 ± 0.6[4,5] $kcal·mol^{-1}$.

Sublimation and Vaporization Data

Vaporization of Al_2O_3(α) and Al_2O_3(l) has been studied by several methods.[12-22] Additional references are cited by Farber *et al.*[14] and Burns.[16] Vaporization is sometimes considered to be congruent but the vapor composition is complex.[14,16] Atomic species predominate below T_{fus}, but molecular species (e.g., AlO and Al_2O) become increasingly important at higher temperatures. For the crystal the average vaporization coefficient is $\alpha < 0.3$.[12,14-16] The rate of evaporation increases discontinuously during melting by radiative heating; this has been attributed to a change in α[16] or to a change in absorbance and emittance.[19] Other work[11] suggests that the radiative properties change on melting. Container materials such as Mo or W cause changes in the partial pressures of O, Al and the molecular species observed in effusion studies;[14,16,21] these effects can be predicted with a model developed by Banon *et al.*[20] Partial pressures reported[14,22] for all observed vapor species yield an overall O/Al ratio of −1.1 instead of the value 1.5 required for congruent vaporization; however, these data do not yield a definite conclusion about congruency due to their relatively large uncertainties.

$S°(298.15\ K) = 93.22 \pm 0.4\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = -2575.16 \pm 2.1\ kJ \cdot mol^{-1}$

$\Delta_f H°(298.15\ K) = -2592.07 \pm kJ \cdot mol^{-1}$

Enthalpy of Formation

The heat of the reaction Al_2O_3(cr, α) + SiO_2(quartz) → Al_2SiO_5 (andalusite) has been determined at 968 K by Holm and Kleppa[1,2] to be -1.99 ± 0.17 kcal·mol^{-1}. This value was obtained from heat of solution measurements in a high temperature oxide melt calorimeter. Using the JANAF functions, this reduces to $\Delta_f H°(298.15\ K) = -1.42$ kcal·mol^{-1} which is used to calculate the adopted value for the enthalpy of formation.

The above value is in serious disagreement with the solution data of Neumann;[3] this work, however, has recently been questioned by several workers. Flood *et al.*[4] suggested that $\Delta_f H°$ was between 0 and -10 kcal·mol^{-1}. Pankratz *et al.*[5] conclude that $\Delta_f H°$ should lie between 0 and -6 kcal·mol^{-1}. Waldbaum[6] calculated $\Delta_f H° = -1.108$ kcal·mol^{-1} from high temperature–high pressure equilibria. These latter values are all in good agreement with the adopted calorimetric value.

Heat Capacity and Entropy

The low temperature heat capacity has been measured from 54.9 to 296.2 K by Todd.[7] The entropy is based on $S°(51\ K) = 0.62$ cal·K^{-1}·mol^{-1}. The high temperature enthalpy has been measured to 1600 K by Pankratz *et al.*[5] The low and high temperature data were joined smoothly together by means of a Shomate function plot.[8] Since all the aluminum and silicon atoms occupy differently coordinated sites, there is no possibility of any residual entropy of mixing in this polymorph.

$S°(298.15\ K) = 83.815 \pm 0.4\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = -2576.37 \pm 2.1\ kJ \cdot mol^{-1}$

$\Delta_f H°(298.15\ K) = -2594.33 \pm 2.1\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The heat of the reaction Al_2O_3(cr, α) + SiO_2(quartz) → Al_2SiO_5(cr, kyanite) has been determined at 968 K by Holm and Kleppa[1, 2] to be -2.37 ± 0.15 kcal·mol^{-1}. This value was obtained from heat of solution measurements in a high temperature oxide melt calorimeter. Using the JANAF functions, this reduces to $\Delta_f H°(298.15\ K) = -1.96$ kcal·mol^{-1}, which is used to calculate the adopted value for the heat of formation of kyanite.

The above value is in serious disagreement with the solution data of Neumann.[3] This work, however, has recently been questioned by several workers. Flood and Knapp[4] suggested that $\Delta_f H°$ was between 0 and -10 kcal·mol^{-1}. Pankratz Kelley[5] conclude that $\Delta_f H°$ should lie between 0 and -6 kcal·mol^{-1}. From phase equilibria, Haskell and DeVries[6] obtained $\Delta_f H° = -2 \pm 7$ kcal·mol^{-1}. Waldbaum[7] calculated $\Delta_f H° = -0.622$ kcal·mol^{-1} from high temperature–high pressure equilibria. These latter values are all in good agreement with the adopted calorimetric value.

Heat Capacity and Entropy

The low temperature heat capacity has been measured from 54.8 to 296.3 K by Todd.[8] The entropy is based on $S°(51\ K) = 0.33$ cal·K^{-1}·mol^{-1}. The high temperature enthalpy has been measured to 1500K by Pankratz and Kelley.[5] The low and high temperature data were joined smoothly together by means of a Shomate function plot.[9] The high temperature heat capacity has been measured between 100° and 1200°C by Leonidov, Barskii and Khitarov.[10] The values reported are in excellent agreement with the adopted functions. Since the aluminum atoms and the silicon atoms occupy different types of sites there is no possibility of any residual entropy of mixing in this polymorph.

$S°(298.15\ K) = 96.179 \pm 0.4\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = -2572.52 \pm 2.1\ kJ \cdot mol^{-1}$

$\Delta_f H°(298.15\ K) = -2589.10 \pm 2.1\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The heat of the reaction Al_2O_3(cr, α) + SiO_2(quartz) → Al_2SiO_5(sillimanite) has been determined at 968 K by Holm and Kleppa[1,2] to be -1.51 ± 0.15 kcal·mol^{-1}. This value was obtained from heat of solution measurements in a high temperature oxide melt calorimeter. Using the JANAF functions, this reduces to $\Delta_f H°(298.15\ K) = -0.71$ kcal·mol^{-1} which is used to calculate the adopted value for the enthalpy of formation.

The above value is in serious disagreement with the solution data of Neumann;[3] this work, however, has recently been questioned by several workers. Flood and Knapp[4] suggested that $\Delta_f H°$ was between 0 and -10 kcal·mol^{-1}. Pankratz and Kelley[5] conclude that $\Delta_f H°$ should lie between 0 and -6 kcal·mol^{-1}. Waldbaum[6] calculated $\Delta_f H° = -0.356$ kcal·mol^{-1} from high temperature–high pressure equilibria. These latter values are all in good agreement with the adopted calorimetric value.

Heat Capacity and Entropy

The low temperature heat capacity has been measured from 54.4 to 296.5 K by Todd.[7] The entropy is based on $S°(51\ K) = 0.73$ cal·K^{-1}·mol^{-1}. The high temperature enthalpy has been measured to 1500 K by Pankratz and Kelley.[5] The low and high temperature data were joined smoothly together by means of a Shomate function plot.[8] The crystal structure of sillimanite indicates that there is no mixing of the tetra-coordinated aluminum and silicon atoms.[9] Thus there should be no residual entropy at 0 K.

PREVIOUS: September 1966 CURRENT: September 1967

$S°(298.15\ K) = 116.85 \pm 0.21\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = -647.35 \pm 3.8\ kJ \cdot mol^{-1}$

$\Delta_f H°(298.15\ K) = -651.03 \pm 3.8\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The adopted value for $\Delta_f H°(298.15\ K)$ is taken from the recent solution calorimetric studies of Ko *et al.*[1] The discrepancy between this value and other measured values is quite large. Korshunov[2] and Kapustinskii and Golutvin[3] determined values of $\Delta_f H°(298.15\ K) = -121.5 \pm 0.4\ kcal \cdot mol^{-1}$ and $-172.9 \pm 4.3\ kcal \cdot mol^{-1}$, respectively, by direct combination of the elements. Sabatier[4] measured a value of $-75.0\ kcal \cdot mol^{-1}$ for the reaction $Al_2S_3(cr) + 3H_2O(l) \rightarrow Al_2O_3 3H_2O(cr) + H_2S(g)$. The heat of formation of Al_2S_3 based on this heat has been widely quoted[1, 5] as $-140.5\ kcal \cdot mol^{-1}$ which is an apparent misinterpretation. Sabatier gives a value of $\Delta_f H°(298.15\ K) = -124.4\ kcal \cdot mol^{-1}$ based on heats of formation for the other materials as accepted at that time. Our reanalysis of Sabatier's data using currently accepted heats of formation[6, 7] yields $\Delta_f H°(298.15\ K) = -148.0\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The adopted $C_p°$ data are based on the low temperature $C_p°$ measurements (12–312 K) of Ho *et al.*[1] and the high temperature enthalpy measurements (403–852 K) of Ferrante and McCune.[8] We have not reanalyzed these results except to extrapolate them to higher temperature. The entropy is based on $S°(15\ K) = 0.046\ cal \cdot K^{-1} \cdot mol^{-1}$.

Phase Data

This table is for the hexagonal phase of Al_2S_3 usually designated as the α phase.[8] Other phases known to exist at higher temperatures are the rhombohedral (γ) and face centered cubic phases. Ferrante and McCune[8] observed an extra enthalpy effect at 878.5 K which they confirmed to be partial conversion to the metastable γ phase via X-ray diffraction. They further showed via X-ray techniques that conversion to the γ phase is essentially complete after heating in the 1320–1500 K range. They were unable to measure the enthalpy of the γ phase since conversion to the γ phase appears to be slow and rapid quenching in the drop calorimeter leads to mixed phases. The α–γ transition temperature was reported as 1273 K[9] and melting points of 1403 K[10] and 1373 K[9] were reported.

PREVIOUS: CURRENT: December 1979

$S°(298.15\ K) = 483.54 \pm 0.8\ J·K^{-1}·mol^{-1}$
$T_{tus} = 1010 \pm 2\ K$

$\Delta_f H°(0\ K) = -7554.7 \pm 16\ kJ·mol^{-1}$
$\Delta_f H°(298.15) = -7581.4 \pm 16\ kJ·mol^{-1}$
$\Delta_{fus} H° = 228.9 \pm 8\ kJ·mol^{-1}$

Enthalpy of Formation

Our adopted value of the heat of formation, $\Delta_f H°(Na_5Al_3F_{14}, cr, 298.15\ K) = -1812.0 \pm 4\ kcal·mol^{-1}$ is based on the emf work of Dewing.[1] Dewing used solid–electrolyte emf cells of the type Al/Na_3AlF_6, $Na_5Al_3F_{14}/Na$ /$Na_5Al_3F_{14}$, AlF_3/Al to determine the free energies for the reaction 5 NaF(cr) + 3 AlF_3(cr) = $Na_5Al_3F_{14}$(cr) over the range 844–996 K. Based on Dewing's[1] reported $\Delta_r G°$ values (20 points), we evaluate $\Delta_r H°(298.15\ K) = -36.58 \pm 0.36\ kcal·mol^{-1}$ and $-39.97 \pm 0.42\ kcal·mol^{-1}$ by the 2nd and 3rd law methods, respectively. From the 3rd law value, we calculate $\Delta_f H°(Na_5Al_3F_{14}, cr, 298.15\ K) = -1811.95 \pm 2.1\ kcal·mol^{-1}$. There has been some confusion over the exact reaction to which Dewing's $\Delta_r G°$ values apply. Both Dewing[1] and Stuve and Ferrante[2] applied the reported $\Delta_r G°$ values to the erroneous reaction 3 Na_3AlF_6(cr) = $Na_5Al_3F_{14}$(cr) + 4 NaF(cr). Our adopted heat of formation is 58 $kcal·mol^{-1}$ less stable than their reported values.[1,2]

Holm[3] estimated $\Delta_r H°(910\ K) = -2.7 \pm 1.2\ kcal·mol^{-1}$ for the reaction 5/8 NaF(cr) + 3/8 AlF_3(cr) = 1/8 $Na_5Al_3F_{14}$(cr). Converting to a molar basis, we obtain $\Delta_f H°(910\ K) = -21.6 \pm 10\ kcal·mol^{-1}$ for the reaction 5 NaF(cr) + 3 AlF_3(cr) = $Na_5Al_3F_{14}$(cr). Using JANAF enthalpies[4] and auxiliary data from,[4,5] we obtain $\Delta_f H°(Na_5Al_3F_{14}, cr, 298.15\ K) = -1791.7 \pm 12\ kcal·mol^{-1}$.

Grjotheim *et al.*[6] studied the vapor pressures over the solid systems $Na_5Al_3F_{14}/AlF_3$ and $Na_5Al_3F_{14}/Na_3AlF_6$ by the weight–loss effusion method. Their results are in good agreement with the mass–spectrometric observations of Sidorov *et al.*[7] on similar systems. Results have been sumamrized by Grjotheim *et al.*[6] who obtained $\Delta_r H°(910\ K) = 60.65 \pm 1.5\ kcal·mol^{-1}$ for the reaction 1/5 $Na_5Al_3F_{14}$(cr) + 2/5 AlF_3(cr) = $NaAlF_4$(g). Using JANAF enthalpies[4] and $\Delta_f H°(298.15\ K)$ values from,[4,5] we obtain $\Delta_f H°(Na_5Al_3F_{14}, cr, 298.15\ K) = -1831.0 \pm 20\ kcal·mol^{-1}$. Similarly, Grjotheim *et al.*[6] obtained $\Delta_r H°(910\ K) = 59.74 \pm 2.0\ kcal·mol^{-1}$ and recalculated $\Delta_r H°(910\ K) = 60.4 \pm 2\ kcal·mol^{-1}$ from the data of Sidorov *et al.*[7] for the reaction 1/2 $Na_5Al_3F_{14}$(cr) = 1/2 Na_3AlF_6(cr) + $NaAlF_4$(g). Using the same auxiliary data as above, we obtain $\Delta_f H°(Na_5Al_3F_{14}, cr, 298.15\ K) = -1808.3 \pm 10\ kcal·mol^{-1}$ from[6] and $\Delta_f H°(Na_5Al_3F_{14}, cr, 298.15\ K) = -1809.6 \pm 10\ kcal·mol^{-1}$ from.[7] These results are in very good agreement with the recalculated value from Dewing.[1]

Heat Capacity and Entropy

Low–temperature heat capacities of chiolite were determined by Stuve and Ferrante[2] by adiabatic calorimetry over the range 5.83–315.75 K. A slight bump was noted in the heat capacity curve between 140 and 175 K. $S°(298.15\ K) = 115.57 \pm 0.2\ cal·K^{-1}·mol^{-1}$ is based on $S°(5\ K) = 0.022\ cal·K^{-1}·mol^{-1}$ obtained by extrapolating the function C_p/T versus T^{2}.[2] $H°(298.15\ K)–H°(0\ K) = 19.338\ kcal·mol^{-1}$.

High temperature enthalpies were measured by Stuve and Ferrante[2] (402.8–991.5 K) and by Holm[3] (677.0–931.7 K). The data of Holm are consistently higher (2.3 ± 0.3 kcal, corresponding to 3–4%) than the data of Stuve and Ferrante and show more scatter. This positive bias ascribed to the calorimeter of Holm was also evident in a study on cryolite (see the Na_3AlF_6, cr, β table). We adopt heat capacities for chiolite based on the drop calorimetry work of Stuve and ferante.[2]

Fusion Data

Chiolite is the mineral name for $Na_5Al_3F_{14}$ (corresponds to 5 NaF + 3 AlF_3). The crystals are tetragonal, space group P_4/mnc.[8] Chiolite melts incongruently at 1010 K[1,3,6] to a combination of cryolite and AlF_3. The value of $\Delta_{fus} H°$ for this process is calculated as the difference between the enthalpies of the crystal and liquid at 1010 K.

$S°(298.15\ K) = [532.124]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1010 \pm 2\ K$

$\Delta_f H°(298.15\ K) = [-7497.408]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 228.9 \pm 8\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(Na_5Al_3F_{14}, l, 298.15\ K)$ is calculated from $\Delta_f H°(Na_5Al_3F_{14}, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus} H°$, and the difference in enthalpy, $H°(1010\ K) - H°(298.15\ K)$, between the crystal and liquid.

Hong and Kleppa[2] measured the enthalpies of mixing for the reaction 5/8 NaF(l) + 3/8 AlF (cr) = 1/8 $Na_5Al_3F_{14}$(l) as $\Delta_r H°(298.15\ K) = -0.591\ kcal·mol^{-1}$. Converting to a molar basis, we obtain $\Delta_r H°(1298\ K) = -4.725\ kcal·mol^{-1}$ for the reaction 5 NaF(l) + 3 AlF_3(cr) = $Na_5Al_3F_{14}$(l), using JANAF data[1] for the enthalpies of formation from JANAF[1] and NBS,[3] we obtain $\Delta_f H°(Na_5Al_3F_{14}, l, 298.15\ K) = -1793.5 \pm 10\ kcal·mol^{-1}$.

Hong and Kleppa[4] also measured the enthalpy of mixing for the reaction 5/9 Na_3AlF_6(l) + 4/9 AlF_3(cr) = 1/3 $Na_5Al_3F_{14}$(l) as $\Delta_r H°(1298\ K) = 4.49\ kcal·mol^{-1}$. Converting to a molar basis, we obtain $\Delta_r H°(1298\ K) = 40.40\ kcal·mol^{-1}$ for the reaction 5 Na_3AlF_6(l) + 4 AlF_3(cr) = 3 $Na_5Al_3F_{14}$(l). Using enthalpies from JANAF[1] and enthalpies of formation from JANAF[1] and NBS,[3] we obtain $\Delta_f H°(Na_5Al_3F_{14}, l, 298.15\ K) = -1794.1 \pm 10\ kcal·mol^{-1}$. These results are in good agreement with adopted enthalpy of formation.

Heat Capacity and Entropy

High temperature enthalpies were measured by drop calorimetry by Holm,[5] (1046.6–1172.9 K). Our analysis of his experimental data leads to a constant heat capacity of 232.76 $cal·K^{-1}·mol^{-1}$. We have corrected his experimental enthalpies for what we believe to be a positive bias by subtracting 2.3 $kcal·mol^{-1}$ from his measured data. Our adopted enthalpies can be represented by the equation $H°(T) - H°(298.15\ K) = -88{,}000 + 232.76\ T\ cal·mol^{-1}$ (1010–1200 K). A hypothetical glass transition is assumed at 650 K. The $C_p°$ values above 1172.9 K are obtained by linear extrapolation. The entropy, $S°(298.15\ K)$, is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

Refer to the crystal table for details.

$S°(298.15\ K) = 175.55 \pm 0.3\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 2186 \pm 10\ K$

$\Delta_f H°(0\ K) = -5585.7 \pm 5\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -5624.1 \pm 5\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = [402]\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(Al_6BeO_{10}, cr, 298.15\ K)$ is calculated from $\Delta_f H°(298.15\ K) = 2.71 \pm 0.45$ kcal·mol^{-1} for $BeO(cr, \alpha) + 3\ Al_2O_3(cr, \alpha) \rightarrow Al_6BeO_{10}(cr)$ using current value of $\Delta_f H°$ for the reactants.[1] $\Delta_r H°$ is based on the value 2.9 ± 0.45 kcal·mol^{-1} at 968 K determined by Holm and Kleppa[2] from the difference in heats of solution of the three components in an oxide melt.

For comparison with the above reaction, we derive $\Delta_f H°(298.15\ K) = 0.6$ kcal·mol^{-1} from $\Delta_f G°(1800\ K) = -3.95$ kcal·mol^{-1} based on equilibrium data. Young[3] used water vapor as a carrier gas to determine the transport of BeO, presumably as $Be(OH)_2$, in equilibrium with BeO(cr) and Al_6BeO_{10}(cr). The difference between the two equilibria gives the above reaction. We compare at 1800 K, near the upper limit of the data, where the experimental method is most sensitive. The resulting difference in $\Delta_f H°(298.15\ K)$ is -2.1 kcal·mol^{-1}, roughly twice the uncertainty claimed for $\Delta_f G°$.[3]

Heat Capacity and Entropy

$C_p°$ and the derived properties below 298.15 K are taken from calorimetric data (15–380 K) of Furukawa and Saba.[4] The entropy is based on $S°(15\ K) = 0.011$ cal·K^{-1}·mol^{-1}. The heat capacity is extrapolated above 1200 K by comparison with current values[1] for $BeAl_2O_4$(cr), Al_2O_3(cr, α), and BeO(cr, α).

Holm and Kleppa[2] combined their $\Delta_f H°$ for formation from the oxides with the corresponding $\Delta_f G°$ from Young[3] in order to calculate $\Delta_f S°$. Based on the present functions and Young's result at 1800 K, we calculate an entropy which is 1.2 cal·K^{-1}·mol^{-1}larger than the adopted calorimetric value. To explain the difference, Holm and Kleppa[2] proposed Be–Al disorder in the crystal, which might provide extra entropy up to 2.76 cal·K^{-1}·mol^{-1}. Crystal structure data were recently published [6], but they do not appear to be sufficient to test the hypothesis of disorder. Although we believe that the discrepancy is within the uncertainty of the equilibrium data, further information is desirable.

Fusion Data

PREVIOUS: CURRENT: June 1972

$S°(298.15\ K)$ = [314.903] $J·K^{-1}·mol^{-1}$ $\Delta_f H°(298.15\ K)$ = [−5299.312] $kJ·mol^{-1}$

T_{fus} = 2186 ± 10 K $\Delta_{fus}H°$ = [402] $kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(Al_6BeO_{10}, l, 298.15\ K)$ is calculated from $\Delta_f H°(Al_6BeO_{10}, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus}H°$, and the difference in enthalpy, $H°(2186\ K)$–$H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

$C_p°$ is assumed to be 136 $cal·K^{-1}·mol^{-1}$, corresponding to 8 $cal·K^{-1}$ g–atom^{-1}, by analogy with current tables[1] for $BeAl_2O_4$(l) and Al_2O_3(l). Below the assumed glass transition at 1400 K, $C_p°$ is taken to be the same as that of the crystal. The entropy is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

T_{fus}, adjusted to IPTS–68, is from the phase study of Lang *et al.*[2] $\Delta_{fus}H°$ is estimated as being slightly smaller than the sum of $\Delta_{fus}H°$ for the component oxides.[1] Data for $BeAl_2O_4$ are consistent with this approach.

$S°(298.15\ K) = 274.9 \pm 12\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 2123 \pm 15\ K$

$\Delta_f H°(0\ K) = -6775.17 \pm 6.3\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -6819.21 \pm 6.3\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The heat of the reaction 3 Al_2O_3(cr, α) + 2 SiO_2(quartz) → $Al_6Si_2O_{13}$(cr) has been determined at 968 K by Holm and Kleppa[1, 2] to be +5.44 ± 0.35 kcal·mol^{-1}. This value was obtained from heat of solution measurements in a high temperature oxide melt calorimeter. Using the JANAF functions, this reduces to $\Delta_f H°(298.15\ K) = 6.77$ kcal·mol^{-1}, which is used to calculate the adopted value for the enthalpy of formation.

Heat Capacity and Entropy

The low temperature heat capacity and high temperature enthalpy of mullite have been measured by Pankratz *et al.*[3] The low temperature investigations extended from 53.5 K to 296.4 K; the Debye–Einstein equation 3D(182/T) + 15E(350/T) + 10E(502/T) + 15E(897/T) represented the data from 53.5 to 114.6 K within 1.4 percent and gave a smooth extrapolation to zero. From this equation, the entropy at 51 K was found to be 2.17 cal·K^{-1}·mol^{-1} as opposed to the value 1.96 cal·K^{-1}·mol^{-1} found by Pankratz *et al.*[5] However, since it is known that mullite has some of its Al atoms on Si sites, there will be configurational entropy remaining at 0 K. This is borne out by the free energy determinations of Rein and Chipman[4] and Kay and Taylor,[5] who obtain $\Delta_f G°(1823\ K) = -5.7 \pm 0.1$ kcal·mol^{-1} for the formation from oxide. If the entropies and enthalpies reported by Pankratz *et al.* are used with the heat of formation, they yield $\Delta_f G°(1823\ K) = +2.9$ kcal·mol^{-1}. Holm and Kleppa[1,2] calcualte that random mixing of tetra-coordinated aluminum and silicon atoms could produce 7 cal·K^{-1}·mol^{-1} residual entropy. We have added 4.7 cal·K^{-1}·mol^{-1} in order to match the measured $\Delta_f G°(1823\ K)$.

A review of the enthalpy determination indicated that the values might easily be 2 percent low if as little as 4 percent of kyanite remained unchanged in the sample used for measurement. Since X-ray could not detect this amount, it is not an unreasonable assumption. Accordingly, we have checked the effect of increasing the heat capacity above 298.15 K by 2 percent; this then gives $\Delta_f G°(1823\ K) = -2.10$ kcal·mol^{-1}. In order to bring this within reasonable agreement with the observations, a residual configurational entropy of 2 cal·K^{-1}·mol^{-1} would be needed. Thus the uncertainty in the residual entropy is of the order of 2 cal·K^{-1}·mol^{-1} due to possible uncertainty in the high temperature heat capacity.

Fusion Data

The congruent melting point of mullite was reported by Aramaki and Roy.[6]

0 to 6000 K Ideal Monatomic Gas

IP(Ar, g) = 12710 ± 0.1 cm^{-1}
$S°(298.15\ K) = 154.845 \pm 0.003\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = 0\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = 0\ kJ \cdot mol^{-1}$

Electronic Levels and Quantum Weights

State	ϵ_i, cm^{-1}	g_i
$^1S_0$	0	1

Enthalpy of Formation

Zero by definition.

Heat Capacity and Entropy

Information on the electronic energy levels and quantum weights is taken from Moore.[1,9] All predicted levels have been observed for n=3 and 4 but above that many predicted levels are missing. Our calculations indicate that any reasonable method of filling in these missing levels and cutting off the summation in the partition function[2] has no effect on the thermodynamic properties to 6000 K. This is undoubtedly a result of the high energy of these levels; the first excited level is over 93000 cm^{-1} above the ground state. Therefore, we list the ground state only. Extension to higher temperatures may require consideration of excited states and utilization of different fill and cutoff procedures.[2]

The thermodynamic functions at 298.15 K agree exactly with recent CODATA recommendations[3] except for two minor differences. First, the entropy differs by 0.1094 $J \cdot K^{-1} \cdot mol^{-1}$ because this table uses a standard-state pressure of 1 bar, whereas the CODATA recommendations are based on 1 atm. Second, entropy differences of the order of 0.001–0.004 $J \cdot K^{-1} \cdot mol^{-1}$ for the rare gases arise due to the use of slightly different values for R; this table uses R = 8.31441 $J \cdot K^{-1} \cdot mol^{-1}$. Considering these minor changes, this table agrees within the estimated uncertainty with those by Hultgren *et al.*,[4] McBride *et al.*,[5] Gurvich *et al.*,[8] and Wagman *et al.*[12] The estimated uncertainty is due to uncertainties in the relative atomic mass and fundamental constants which are based on the 1981 scale[6] and the 1973 values,[7] respectively.

Phase Data

The triple point, 83.798 K, and boiling point, 87.294 K, are a defining fixed point and a secondary reference point, respectively of IPTS–68.[10,11] Hultgren *et al.*[4] had recommended a triple point of 83.81 K (0.6801 atm) and a boiling point of 87.30 K (1 atm). These values are provided for the convenience of the reader and have not been evaluated by the present authors. As a result of these low values, the reference state for argon is chosen to be the ideal gas at all temperatures. This may differ from the choice of other authors.

Enthalpy of Formation

The ionization limit of neutral argon (127109.9 ± 0.1 cm^{-1}) reported by Moore[1] is adopted as $\Delta_f H°(0\ K)$ for $Ar^+(g)$. The ionization limit is converted from cm^{-1} to $kJ \cdot mol^{-1}$ using the factor, 1 cm^{-1} = 0.01196266 $kJ \cdot mol^{-1}$, which is derived from the latest CODATA fundamental constants.[2] The uncertainty in the ionization limit corresponds to an uncertainty of ±0.001 $kJ \cdot mol^{-1}$ in the heat of formation. Rosenstock *et al.*[9] and Levin and Lias[11] have summarized additional ionization potential and appearance potential data. A recent atomic spectroscopic study by Minnhagen[12] yielded an ionization potential within 0.13 cm^{-1} of our adopted value. Gurvich *et al.*[8] and Wagman *et al.*[10] adopted the same ionization potential, but the use of slightly different fundamental constants by Wagman *et al.*[10] resulted in a heat of formation difference of 0.015 $kJ \cdot mol^{-1}$.

$\Delta_f H°(Ar^+, g, 298.15\ K)$ is obtained from $\Delta_f H°(Ar, g, 0\ K)$ by using IP(Ar) with JANAF[3] enthalpies $H°(0\ K) - H°(298.15\ K)$ for $Ar^+(r)$, Ar(g), and $e^-(r)$. $\Delta_r H°(Ar \rightarrow Ar^+ + e^-, 298.15\ K)$ differs from a room temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[9] $\Delta_f H°(298.15\ K)$ should be changed by −6.197 $kJ \cdot mol^{-1}$ if it is to be used in the ion convention that excludes the enthalpy of the electron.

Heat Capacity and Entropy

The information on electronic energy levels and quantum weights given by Moore[4] is incomplete because many theoretically predicted levels have not been observed. Our calculations indicate that any reasonable method of filling in these missing levels and cutting off the summation in the partition function[5] has no effect on the thermodynamic functions to 6000 K. This is a result of the high energy of all levels other than the ground state and the $^2P_{1/2}$ level; the next lowest level is over 108000 cm^{-1} above the ground state. Since inclusion of these upper levels has no effect on the thermodynamic functions (to 6000 K), we list only the ground state and the $^2P_{1/2}$ state, with the energy of the latter state taken from a more recent study by Moore.[1] The reported uncertainty in $S°(298.15\ K)$ is due to uncertainties in the relative ionic mass and fundamental constants. Extension of these calculations above 6000 K may require consideration of the higher excited states and use of different fill and cutoff procedures.[5]

The thermodynamic functions reported here agree with those of Green *et al.*,[6] Hilsenrath *et al.*,[7] and Gurvich *et al.*[8] except for one or two minor changes. First, the entropy differs by 0.1094 $J \cdot K^{-1} \cdot mol^{-1}$ because this table uses a standard-state pressure of 1 bar, whereas the cited references used a pressure of 1 atm. Second, smaller differences arise from the use of slightly different values for the fundamental constants, the relative ionic mass, and the position of the $^2P_{1/2}$ electronic level.

$S°(298.15\ K) = 5.83 \pm 0.08\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 2350 \pm 50\ K$

$\Delta_f H°(0\ K) = 0\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = 0\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 50.2 \pm 1.7\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Zero by definition.

Heat Capacity and Entropy

The adopted low temperature heat capacity values ($T < 298.15$ K) are based on the heat capacity studies of Biler,[1,2] Johnston *et al.*,[3] and Bogdanov *et al.*[4] The adopted high temperature heat capacities ($T > 298.15$ K) are derived from the enthalpy studies of McDonald and Stull[5] and Stout *et al.*[6] The mathematical and graphical treatment of these five studies, providing experimental measurements in the 2–2218 K range, yield a continuous and smooth heat capacity curve. The resulting entropy, $S°(298.15\ K) = 5.83 \pm 0.08\ J \cdot K^{-1} \cdot mol^{-1}$, is 0.07 $J \cdot K^{-1} \cdot mol^{-1}$ less than the CODATA recommended entropy[7] due to the differing interpretation of the C_p results for T<50 K. In this analysis, the scatter in the experimental data obscures any differences that may arise in the thermal functions due to crystallographic differences in the various crystalline samples.

Biler[1,2] measured the heat capacity of B(cr, β) in the region 2–15 K. He reported $\theta_D = 1480$ K derived from his extrapolation to $T/K = 0$ of a graph of $(C_p - \gamma T)/T^3$ vs T^2. For boron, there is no electronic contribution, i.e. $\gamma = 0$. Only graphical data was presented. The sample, stated to be the β-rhombohedral modification based on X-ray data, contained 50 ppm Cu whereas the other impurities were reported as <1ppm (via electron micro-probe analysis).

Johnston *et al.*[3] measured 46 heat capacity values in the range 16.90–303.71 K. This study indicated a shallow maximum near 25 K at which temperature $C_p° = 0.038\ J \cdot K^{-1} \cdot mol^{-1}$. A graph of the results by Biler[1,2] tends to agree with the observations of Johnston *et al.*[3] and to support the presence of a C_p anomaly. The purity of Johnston's sample was not reported. Hultgren *et al.*[8] stated that the sample was of the tetragonal (α) modification. This inference is presumably based on Johnston's reported method of preparation and X-ray data.

Bogdanov *et al.*[4] measured the heat capacity from 16 to 280 K. Metallic impurity content was stated to be <0.01 %. X-ray analysis was used to infer that the sample was the β-polymorph. Bogdanov *et al.* also inferred that the sample of Johnston *et al.* was not of a specific crystalline modification. They surmised that impurities caused the shallow maximum seen by Johnston *et al.*[3] near 25 K. Bogdanov *et al.* found no maximum, but their smooth values level out below 40 K in contradiction to theory. Their last five values (20–40 K) vary linearly with T and extrapolate to $C_p = 0.0126\ J \cdot K^{-1} \cdot mol^{-1}$ at $T/K = 0$. The authors did not publish their experimental data, so it is difficult to interpret this behavior. It may arise from bias of their calorimeter near its limit of sensitivity or from anomalous behavior of their sample.

McDonald and Stull[5] measured enthalpies in a copper block drop calorimeter, 20 points in the range 282.8 to 1667.8 K. The sample was reported to be the β-rhombohedral form (based on X-ray data) with a metallic impurity of 0.59%. Stout *et al.*,[6] also using a copper block drop calorimeter, measured enthalpies, five data points in the range 1820–2218 K. The sample was reported to have 0.04% metallic impurities and to contain 300 ppm O and 6300 ppm C. No information as to crystalline form was given. Wise *et al.*[9] measured the enthalpy of two crystalline boron samples (each reportedly containing some of the β-modification) in the temperature range 515–1103 K.

The adopted heat capacity values below 25 K are derived from the θ_D value of Biler.[1,2] From 25 K to 300 K, the derived values are a compromise of the data of Johnston *et al.*[3] and Bogdanov *et al.*,[4] but excluding in each the effect of the possible anomalous behavior. In the region 25 to 95 K, there is large scatter in each data set, so that large deviations occur, up to 23%. In the region 95–300 K, Johnston's data shows deviations of −2.1 to +1.8% while Bogdanov's data shows derviations of −2.9 to +1.7% from the adopted values. The two sets of data are intertwined, one is not always above the other.

In the enthalpy data, 26 of the 30 points of McDonald and Stull[5] are within +0.6% to −0.5%. Stout's[6] data deviates from −0.7% at 1819.5 K to +0.7% at 2217.7 K. The data of McDonald and Stull and Stout *et al.* are slightly skewed to each other. The observed enthalpies of McDonald and Stull[5] fall between the enthalpies of the two samples measured by Wise *et al.*[9]

Other heat capacity and enthalpy studies are available but were excluded from this analysis. A detailed discussion of the Group IIIA metals (B, Al, and Ga) is in preparation by the JANAF staff.

Fusion Data

Refer to the liquid table for details.

Sublimation Data

The adopted value of $\Delta_{sub} H°(298.15\ K)$ is the value recommended by CODATA.[7] See the ideal gas table for details.

PREVIOUS: March 1979 CURRENT: June 1983

$S°(298.15\ K) = [26.555]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 2350 \pm 50\ K$

$\Delta_f H°(298.15\ K) = [48.927]\ kJ·mol^{-1}$
$\Delta_{fus}H° = 50.2 \pm 1.7\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of formation of liquid boron is calculated from that of the crystal (β–rhomohedral) by adding $\Delta_{fus}H°$ and the difference in enthalpy, $H°(2350\ K)–H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

There are no heat capacity or enthalpy studies which adequately define the liquid phase heat capacity values. Tsagareishvili and Tsagareishvili[1] estimated $C_p°(l) = 39.04\ J·K^{-1}·mol^{-1}$ at T_{fus} by means of quasi–thermodynamic correlations. Using our adopted $C_p°$ value for the crystal at T_{fus}, we recalculate this to be $C_p°(l) = 35.98\ J·K^{-1}·mol^{-1}$ at T_{fus}. This value appears to be too large. Even though B(cr) and Al(cr) have different crystal structures, the heat capacity values of the crystals at their respective T_{fus} are very similar, $30.64\ J·K^{-1}·mol^{-1}$ for B(β–cr) and $32.96\ J·K^{-1}·mol^{-1}$ for Al(cr). We estimate that the B(l) heat capacity is $31.75\ J·K^{-1}·mol^{-1}$, as is the value for Al(l).

A glass transition is assumed at 1760 K. The entropy at 298.15 K is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

The adopted value for the melting point of β–rhombohedral boron is $T_{fus} = 2350 \pm 50$ K. This value is within 2 K of the value recommended by Charlesworth.[2] The value is based primarily on the work of Kimpel and Moss.[3] These authors[3] used a disappearing hole technique to measure $T_{fus} = 2352 \pm 20$ K for a 99.5% pure sample. Other studies are by Wisnyi and Pijanowski[4] (2313 ± 30 K), Cueilleron[5] (2273–2348 K), and Mar[6] (2315 ± 20 K).

The enthalpy of melting was measured by Stout et al.[7] using drop calorimetry. The enthalpy of melting, $\Delta_{fus}H° = 50.2 \pm 1.7\ kJ·mol^{-1}$, was the result of three calorimetric determinations involving different samples and containers. It leads to an entropy of fusion, $\Delta_{fus}S° = 21.4\ J·K^{-1}·mol^{-1}$, which is more than twice as large as previous estimates.

Vaporization Data

There are no vaporization studies involving liquid boron. The boiling point, T_{vap}(1 bar) = 4137.895 K, is calculated as the temperature for which $\Delta_f G°=0$ for B(l)=B(g). The difference in the enthalpy of formation of B(l) and B(g) at T_{vap} is the enthalpy of vaporization, $\Delta_{vap}H° = 480.344\ kJ·mol^{-1}$.

Enthalpy of Formation

The enthalpy of formation is derived from the measurements of Paule and Margrave,[1] Robson and Gilles,[2] Hildenbrand and Hall,[3] Akishin *et al.*,[4] and Schissel and Trulson.[5] $\Delta_f H°$(B, g, 298.15 K) = 560 ± 12 $kJ·mol^{-1}$ is the value recommended by CODATA.[6] CODATA stated that these measurements were selected from the many sets of data available as being the most self-consistent. The difference in $S°$(B, cr, 298.15 K) between our adopted value and that of CODATA,[6] will create a change of less than 0.2 $kJ·mol^{-1}$ in $\Delta_f H°$(B, g, 298.15 K). Not included in this analysis are other vaporization studies by Trulson *et al.* (1923–2249 K),[7] Burns *et al.* (2403 K),[8] Mar and Bedford (1823–2253 K),[9] and Storms and Mueller (1750–2050 K).[10] The two latter studies were published after the time of the CODATA analysis. Inclusion of these studies would suggest a somewhat larger value for $\Delta_f H$. The $\Delta_f H°$(B, g, 298.15 K) values reported by Mar and Bedford[9] are 563.6 ± 33.4 $kJ·mol^{-1}$ (2nd law) and 561.1 ± 3.3 $kJ·mol^{-1}$ (3rd law) from torsion data and 566.1 ± 13.3 $kJ·mol^{-1}$ from mass spectrometric data; Storms and Mueller[10] reported 574.9 ± 0.8 $kJ·mol^{-1}$ as the 2nd law value derived from a mass spectrometric study.

Heat Capacity and Entropy

The electronic levels are from the recent analysis by Odintzova and Striganov.[11] Although only the ground state, first two excited states, and the highest observed state (below the ionization limit) are listed, all reported states below the ionization limit are used in the calculations. The 164 observed levels are too numerous to list completely, but do include contributions from observed levels to n=39.

The level at 15.254 cm^{-1} has a large effect on the heat capacity and entropy below 100 K. The heat capacity effect decreases to zero above 600 K where the 15.254 cm^{-1} level is fully populated. The higher excited states affect the heat capacity values above 3000 K. The Gibbs energy function values up to 6000 K are essentially independent of the cut–off procedure, the inclusion of levels for n>2, and the estimated missing levels (for n<39).

The thermal functions at 298.15 K agree with recent CODATA recommendations[1] except for two minor differences. First, the entropy differs by 0.1094 $J·K^{-1}·mol^{-1}$ because this table uses a standard state pressure of 1 bar, whereas the CODATA recommendations are based on 1 atm. Second, an entropy difference of 0.001 $J·K^{-1}·mol^{-1}$ arises due to the use of slightly different values for the fundamental constants.

$^3P_1$	37340.0	3
$^3P_2$	37356.4	5

Enthalpy of Formation

$\Delta_f H°(B^+, g, 0\ K)$ is calculated from $\Delta_f H°(B, g, 0\ K)$[1] using the spectroscopic value of IP(B) = 66928.10 ± 0.1 cm^{-1} (800.638 ± 0.001 kJ·mol^{-1}) from Odintzova and Striganov.[2] The ionization limit is converted from cm^{-1} to kJ·mol^{-1} using the factor, 1 cm^{-1} = 0.01196266 kJ·mol^{-1}, which is derived from the 1973 CODATA fundamental constants.[3] Rosenstock *et al.*[4] and Levin and Lias[5] have summarized additional ionization and appearance potential data.

$\Delta_f H°(B^+, g, 298.15\ K)$ is calculated from $\Delta_f H°(B, g, 0\ K)$ by using IP(B) with JANAF[1] enthalpies, $H°(0\ K)$–$H°(298.15\ K)$, for B(g), B^+(g), and e^-(ref). $\Delta_f H°(B \rightarrow B^+ + e^-, 298.15\ K)$ differs from a room temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[4] $\Delta_f H°(298.15\ K)$ should be changed by −6.197 kJ·mol^{-1} if it is to be used in the ion convention that excludes the enthalpy of the electron.

Heat Capacity and Entropy

The information on electronic energy levels and quantum weights, given by Moore,[6,7] is incomplete because many theoretically predicted levels have not been observed. Our calculations indicate that any reasonable method of filling in these missing levels and cutting off the summation in the partition function[8] has no effect on the thermodynamic functions to 6000 K. This is a result of the high energy of all levels other than the ground state and the first three excited states; the next excited state is 73396.7 cm^{-1} above the ground state. Since inclusion of these excited states has no effect on the thermodynamic functions (to 6000 K), we list only the ground state and the first three excited states. The energies of the ^3P levels are uncertain by 249 cm^{-1}. No intersystem combinations have been observed. The reported uncertainty in $S°(298.15\ K)$ is due to uncertainties in the relative ionic mass and the fundamental constants. Extension of these calculations above 6000 K may require consideration of the excited states and use of different fill and cutoff procedures.[8]

$^3P_2$	9.0	5

Enthalpy of Formation

$\Delta_f H°(B^-, g, 0\ K)$ is calculated from $\Delta_f H°(B, g, 0\ K)$[1] using the adopted election affinity of EA(B) = 0.277 ± 0.010 eV (26.726 ± 0.965 $kJ \cdot mol^{-1}$). This value, recommended by Hotop and Lineberger[2] is based on a laser photodetachment electron spectrometry study.[3] Additional information on B^-(g) may be obtained in the critical discussions of Hotop and Lineberger,[2,4] Rosenstock *et al.*[5] and Massey.[6]

$\Delta_f H°(B^-, g, 298.15\ K)$ is obtained from $\Delta_f H°(B, g, 0\ K)$ by using EA(B) with JANAF [1]enthalpies, $H°(0\ K) - H°(298.15\ K)$, for B^-(g), B(g), and e^-(ref). $\Delta_r H°(B^- \rightarrow B + e^-, 298.15\ K)$ differs from a room-temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[5] $\Delta_f H°(298.15\ K)$ should be changed by +6.197 $kJ \cdot mol^{-1}$ if it is to be used in the ion convention that excludes the enthalpy of the electron.

Heat Capacity and Entropy

The ground state electronic configuration for B^-(g) is given by Hotop and Lineberger,[2,4] Rosenstock *et al.*[5] and Massey.[6] The fine-structure separation has been calculated via an isoelectronic extrapolation of ratios of fine structure separations[4] and is that recommended by Hotop and Lineberger.[2]

A comparison of the isoelectronic sequence B^-(g), C(g), N^+(g), O^{++}(g) would suggest that a state, $^1D_2$, may exist at low energy, 5000 cm^{-1}. However, this is most likely a metastable state lying at an energy greater than the electron affinity. As discussed by Hotop and Lineberger,[2,4] no stable excited states have been observed. Thus we assume no stable excited states exist.

Ground State Quantum Weight: [2] σ = [1]
Point Group: [C_s]
Bond Distances: Be–O = [1.40] Å; O–B = [1.36] Å; B=O = [1.20] Å
Bond Angles: Be–O–B = [120]°; O–B = [180]°
Product of the Moments of Inertia: $I_A I_B I_C = [2.451196 \times 10^{-115}]\ g^3·cm^6$

Enthalpy of Formation

Since Blackburn and Buchler[1] have postulated that the BO_2^- group has the pseudochloride character in bond strength, the enthalpy of formation of $BeBO_2(g)$ is estimated by adding the difference of the enthalpies of formation of BeCl(g) and AlCl(g) to the enthalpies of formation of $AlBO_2(g)$, using all JANAF values: $\Delta_f H°$(BeCl, g, 298.15 K) = 3.0, $\Delta_f H°$(AlCl, g, 298.15 K) = −11.2 and $\Delta_f H°$($AlBO_2$, g, 298.15 K) = −129.4 $kcal·mol^{-1}$.

Heat Capacity and Entropy

All molecular constants are estimated by comparison with those in $LiBO_2(g)$, $AlBO_2(g)$, $B_2O_3(g)$ and BeCl(g). The principal moments of inertia are $I_A = 1.1016 \times 10^{-39}$, $I_B = 14.3762 \times 10^{-39}$ and $I_C = 15.4778 \times 10^{-39}$ $g·cm^2$.

$S°(298.15\ K) = 225.00\ J\cdot K^{-1}\cdot mol^{-1}$

$\Delta_f H°(0\ K) = 239 \pm 42\ kJ\cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = 234 \pm 42\ kJ\cdot mol^{-1}$

Electronic Level and Quantum Weight		
State	ϵ_i, cm^{-1}	g_i
$^1\Sigma^+$	0	1

$\omega_e = 689.04\ cm^{-1}$ $\omega_e x_e = 3.57\ cm^{-1}$ $\sigma = 1$
$B_e = 0.497\ cm^{-1}$ $\alpha_e = 0.0036\ cm^{-1}$ $r_e = 1.887$ Å

Enthalpy of Formation

Herzberg[1] reported $D_0^\circ = 4.1$ eV which corresponds to a enthalpy of formation of 64 kcal·mol^{-1}. Gaydon[2] gives essentially the same value, with a provisor that the value is unreliable due to the ionic nature of the bonding. Barrow[3] made a critical evaluation of the bond dissociation energies of the group III halides and concluded $D_0^\circ(BBr) = 103.5$ which gives $\Delta_f H°(298.15\ K) = 56$ kcal·mol^{-1}. An estimate of the dissociation energy by taking the ratio $D_0^\circ(BF)/[\Delta_{at}H°(BF_3, g, 0\ K)/3] = 1.177$ and applying this to BBr_3 yields $D_0^\circ(BBr) = 103$ kcal·mol^{-1}; this was the value adopted.

Heat Capacity and Entropy

The vibrational and rotational constants are all taken from NBS.[4]

Ground State Quantum Weight: [2] $\sigma = 1$
Point Group: C_s
Bond Distances: B–Cl = [1.73] Å; B–Br = [1.87] Å
Bond Angle: Cl–B–Br = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [2.193041 \times 10^{-114}]\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation is estimated by assuming $\Delta_f H° = 0$ for the reaction $BCl_2(g) + BBr_2(g) = 2\ BBrCl(g)$.

Heat Capacity and Entropy

The vibrational frequencies are estimated by comparison with those for BBr_2 and BCl_2. The bond distances, angles, and quantum weight are assumed the same as in the dihalides. The principal moments of inertia are $I_A = 1.2989 \times 10^{-39}$, $I_B = 40.4453 \times 10^{-39}$, and $I_C = 41.7442 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: [1] $\sigma = 2$

Point Group: C_{2v}

Bond Distances: B–Cl = 1.73 Å; B–Br = 1.87 Å

Bond Angles: Cl–B–Cl = [120]°; Br–B–Cl = [120]°

Product of the Moments of Inertia: $I_A I_B I_C = 9.196849 \times 10^{-113}\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation is estimated by assuming $\Delta_r H° = 0$ for the reaction $BBr_3(g) + 2\ BCl_3(g) = 3\ BBrCl_2(g)$.

Heat Capacity and Entropy

Vibrational frequencies are obtained from Lindeman and Wilson.[1] The b_1 mode was the only unobserved frequency and was calculated from a normal coordinate treatment. Bond distances were reported by Wentink and Tiensuu.[2] Bond angles were estimated by analogy with the other trihalides of boron. The principal moments of inertia are $I_A = 26.4297 \times 10^{-39}$, $I_B = 47.2365 \times 10^{-39}$, and $I_C = 73.6662 \times 10^{-39}\ g·cm^{-1}$.

Ground State Quantum Weight: [2] $\sigma = 1$

Point Group: C_s

Bond Distances: B–F = [1.3] Å; B–Br = [1.87] Å

Bond Angle: Br–B–F = [120]°

Product of the Moments of Inertia: $I_A I_B I_C = [4.131563 \times 10^{-115}]\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation is estimated by assuming $\Delta_f H° = 0$ for the reaction $BBr_2(g) + BF_2(g) \rightarrow 2\ BBrF(g)$.

Heat Capacity and Entropy

The vibrational frequencies, bond lengths, angles and quantum weight are estimated by comparison with the respective dihalides. The principal moments of inertia are $I_A = 0.8401 \times 10^{-39}$, $I_B = 21.7603 \times 10^{-39}$, and $I_C = 22.6004 \times 10^{-39}$ g·cm².

Bond Angles: F–B–F = [120]°; Br–B–F = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = 8.471599 \times 10^{-114}\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation is estimated by assuming $\Delta_f H° = 0$ for the reaction $2\ BF_3(g) + BBr_3(g) \rightarrow 3\ BBrF_2(g)$.

Heat Capacity and Entropy

All but two of the vibrational frequencies have been observed and assigned by Lindeman and Wilson.[1] The two remaining frequencies were calculated by a normal coordinate treatment. The bond distances were reported by Wentink and Tiensuu.[2] The bond angles were estimated by analogy with the other boron trihalides. The principal moments of inertia are $I_A = 7.9360 \times 10^{-39}$, $I_B = 28.9444 \times 10^{-39}$, and $I_C = 36.8805 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: [1] α = 1
Point Group: $[C_v]$
Bond Distances: O–B = [1.20] Å; B–Br = [1.87] Å
Bond Angle: O–B–Br = [180]°
Rotation Constant: B_0 = [0.117436] cm^{-1}

Enthalpy of Formation

The value of $\Delta_f H°$(BOBr, g, 298.15 K) is calculated based on an assumption that $D_0°$(BO–Br) = 92.5 kcal·mol^{-1} which is estimated by comparison with the following related bond energy values: $D_0°(BF_2–F)$ = 159, $D_0°$(BO–F) = 169, $D_0°(BCl_2–Cl)$ = 105, $D_0°$(BO–Cl) = 110 and $D_0°(BBr_2–Br)$ = 90.5 kcal·mol^{-1}.

Heat Capacity and Entropy

The molecular structure is assumed to be linear. The vibrational frequencies (ν) are estimated from the ν values calculated by the valence force method by Herzberg[1] using estimated force constants, $k_1 = 4.2 \times 105$, $k_2 = 16.9 \times 105$ dynes cm^{-1} and $k_g = 0.37 \times 10^{-11}$ dynes·cm·rad^{-1}. The B=O and B–F[1] bond distances are assumed to be the same as those in BO(g) and BBr_3(g), respectively.

Bond Distance: B–Br = [1.87] Å
Bond Angle: Br–B–Br = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [7.270321 \times 10^{-114}]\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation is estimated by analogy with BF_3, specifically the ratio $\Delta_f H°(BX_3 \rightarrow BX_2 + X)/\Delta_f H°(BX_3 \rightarrow B + 3X)$ is taken as 0.347.

Heat Capacity and Entropy

The vibrational frequencies were obtained from force constants transferred from the trihalide given by Herzberg.[1] The bond length is taken between those of the mono and trihalide and the angle is estimated to be the same as that in the trihalides. The ground state quantum weight is taken as two due to the one unpaired electron.

The principal moments of inertia are $I_A = 1.4699 \times 10^{-39}$, $I_B = 69.5984 \times 10^{-39}$, and $I_C = 71.0683 \times 10^{-39}\ g·cm^2$.

166(1)	409(1)

Ground State Quantum Weight: [1] $\sigma = 2$
Point Group: C_{2v}
Bond Distances: B–Br = 1.87 Å; B–Cl = 1.75 Å
Bond Angles: Br–B–Br = [120]°; Cl–B–Br = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = 2.555411 \times 10^{-112}\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation is estimated by assuming $\Delta_r H° = 0$ for the reaction $2\ BBr_3(g) + BCl_3(g) \rightarrow 3\ BBr_2Cl(g)$.

Heat Capacity and Entropy

The vibrational frequencies have all been observed and assigned by Lindeman and Wilson.[1] The bond lengths were reported by Wentink and Tiensuu.[2] Bond angles are estimated by analogy with the other trihalides of boron. The principal moments of inertia are $I_A = 35.0767 \times 10^{-39}$, $I_B = 69.5984 \times 10^{-39}$, and $I_C = 104.6751 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: [1] $\sigma = 2$
Point Group: C_{2v}
Bond Distances: B–Br = 1.87 Å; B–Cl = 1.295 Å
Bond Angles: Br–B–Br = [120]°; Br–B–F = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = 8.725604 \times 10^{-113}\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation is estimated by assuming $\Delta_f H° = 0$ for the reaction 2 $BBr_3(g)$ + $BF_3(g)$ → 3 $BBr_2F(g)$.

Heat Capacity and Entropy

Two of the vibrational frequencies were observed and assigned by Lindeman and Wilson.[1] The remaining frequencies were calculated by a normal coordinate treatment using force constants obtained by comparison with the other mixed trihalides. The bond distances were reported by Wentink and Tiensuu.[2] The bond angles are estimated by analogy with the other trihalides. The principal moments of inertia are $I_A = 14.8465 \times 10^{-39}$, $I_B = 69.5984 \times 10^{-39}$, and $I_C = 84.4449 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: 1 $\sigma = 2$

Point Group: C_{2v}

Bond Distances: B–H = 1.20 Å; B–Br = [1.87] Å

Bond Angles: Br–B–Br = 119.3 ± 2°; Br–B–H = 120.3 ± 1°

Product of the Moments of Inertia: $I_A I_B I_C = 1.096494 \times 10^{-113}\ g^3·cm^6$

Enthalpy of Formation

The value of $\Delta_f H°(BBr_2H, g, 298.15\ K)$ is derived by assuming the B–H bond strength to be 92 $kcal·mol^{-1}$, the same as that in $BCl_2H(g)$.

Heat Capacity and Entropy

The molecular structure, B–H bond distance and bond angle were obtained from Lynds and Bass.[1] The B–Br bond distance is taken from that in $BBr_3(g)$ molecule. The vibrational frequencies adopted and corrected to the average isotopic species were assigned to Brieux de Mandirola and Westerkamp[2] from infrared spectrum. The values in brackets are calculated by the Wilson's FG method. Infrared spectrum of $BBr_2H(g)$ was also reported by Wason and Porter[3] and three frequencies, υ_1, υ_4, and υ_5, were assigned. The principal moments of inertia are: $I_A = 2.2244 \times 10^{-39}$, $I_B = 69.1057 \times 10^{-39}$, and $I_C = 71.3302 \times 10^{-39}\ g·cm^2$.

PREVIOUS: March 1966 (1 atm) CURRENT: March 1966 (1 bar)

$S°(298.15\ K)$ = [228.9] $J·K^{-1}·mol^{-1}$
T_{fus} = 228.9 K

$\Delta_f H°(298.15\ K)$ = [−238.49 ± 0.2] $kJ·mol^{-1}$
$\Delta_{fus}H°$ = Unknown

Enthalpy of Formation

The enthalpy of formation of boron tribromide liquid has been determined by Skinner and Smith[1] by hydrolysis to H_3BO_3 and HBr. The adopted enthalpy of formation is calculated from the hydrolysis data[1] using $\Delta_f H°(H_3BO_3, cr, 298.15\ K)$ from these tables, $\Delta_{sol}H°(H_3BO_3, cr)$, from Fasilino[2] with the dilution data of Smisko and Mason.[3] The $\Delta_f H°$(HBr, aq) was taken from Evans.[4]

Heat Capacity and Entropy

The heat capacity was estimated from that of the gas by Kelley.[5] The entropy is back calculated from that of the gas by adjusting the free energy functions to give the best fit of the vapor pressure data.

Fusion Data

The temperature of melting was reported by Boubeau and Keller,[6] and Stock and Kuss.[7] This value was recently confirmed by the triple point measurement of 227.31 K by Barber, Boynton, and Gallagher.[8]

Vaporization Data

The boiling point is from the data of Stock and Kuss.[7] A 2nd and 3rd law analysis of the vapor pressure data of Stock and Kuss[7] and Barber *et al.*[8] indicated that the data of Stock and Kuss[7] gave the best agreement as indicated below.

Sources	$\Delta_{vap}H°(298.15\ K)$, $kcal·mol^{-1}$ 2nd law	3rd law	
		$S°(298.15\ K)$ = 54.7	$S°(298.15\ K)$ = 54.26
[7]	8.175 ± 0.03	8.222 (−0.02)	8.361 (0.42)
[8]	8.229 ± 0.03	8.203 (−0.44)	8.347 (0.00)

Stock and Kuss[7] had the first eight data points rejected due to a statistical test on the 3rd law values. The values in parentheses are values of the 3rd law drift measured as $\Delta(\Delta H)/\Delta T$. The 2nd law entropy also confirmed the choice of the data of Stock and Kuss[7] and an entropy of 54.7 $cal·K^{-1}·mol^{-1}$.

Ground State Quantum Weight: [1] $\sigma = 6$
Point Group: D_{3h}
Bond Distance: B–Br = 1.87 ± 0.02 Å
Bond Angle: Br–B = 120° ± 6°
Product of the Moments of Inertia: $I_A I_B I_C = 6.742600 \times 10^{-112}\ g^3·cm^6$

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ is obtained from the enthalpy of formation of the liquid plus the heat of vaporization at 298.15 K, taken as 8.20 $kcal·mol^{-1}$ as the average 2nd and 3rd law value derived from the vapor pressures of Stock and Kuss.[1] Refer to $BBr_3(l)$ table for details.

Heat Capacity and Entropy

Vibrational frequencies were obtained from Wentink and Tiensuu[2] and modified for the natural isotopic abundance (^{10}B 18.83%, ^{11}B 81.1%). B–Br bond distance was reported by Wentink and Tiensuu.[2] Br–B–Br angle was taken from Sutton.[3] The principal moments of inertia are $I_A = I_B = 69.5984 \times 10^{-39}$, $I_C = 139.1968 \times 10^{-39}\ g·cm^2$.

Enthalpy of Formation

Dissociation energies of BCl(g) has been reported by Herzberg,[1] Gaydon,[2] and Barrow.[3] The corresponding values of $\Delta_f H°$(BCl, g, 298.15 K) are derived. The results are given as follows:

Source	Dissociation Energy, $D_0°$ eV	$D_0°$ kcal·mol^{-1}	$\Delta_f H°$(298.15 K) kcal·mol^{-1}
[1]	4.2	96.9	62.6
[2]	5.1 ± 0.4	117.6 ± 9.2	41.8 ± 9.2
[3]	—	127	33.8 ± 4

The last value of $\Delta_f H°$(298.15 K) listed in the above table is adopted. Using the bond energy, $D_0°$(B–Cl), obtained from BCl_3(g) molecule, $\Delta_f H°$(298.15 K) for BCl(g) is calculated as 37.8 kcal·mol^{-1} employing the same ratio of $D_0°$(B–X)/ average bond energy of BX_3 as found in BF(g) and BF_3(g), which is within the uncertainty of the value evaluated from dissociation energy.

Heat Capacity and Entropy

The spectroscopic constants are obtained from Herzberg[1] and corrected to the average isotopic species.

Enthalpy of Formation

Several values of the appearance potential of BCl^+ from BCl_3 have been reported. Osberghaus[1] gave 19.2 eV, Marriott and Craggs[2] reported 18.54 ± 0.07 eV, and Koski *et al.*[3] obtained two values of 17.2 ± 0.2 Ev and 20 ± 0.2 eV. We make the presumption that the higher values, 19.2 and 20, refer to the reaction $BCl_3(g) + e^-$, $2\ Cl(g) + 2e^-$ and the other values to $BCl_3(g) + e^- \rightarrow BCl^+ + Cl_2(g) + 2\ e^-$. Using the lower value in each case to help eliminate any excess kinetic energy, we obtain $\Delta_f H°(BCl^+, g, 298.15\ K) = 289$ and 300 $kcal \cdot mol^{-1}$, respectively. We adopt an average value of $\Delta_f H°(BCl^+, g, 298.15\ K) = 295 \pm 10\ kcal \cdot mol^{-1}$, which corresponds to an ionization potential for BCl(g) of 11.3 ± 0.3 eV.

Heat Capacity and Entropy

BCl^+ is isoelectronic with BeCl, and the ground state configuration and electronic levels are estimated by comparison with BeCl. The bond length, frequency and anharmonicity constant are estimated between the value for BCl and BeCl; the rotational constant is calculated from the bond length and atomic masses, and α_e is obtained from the above constants assuming a Morse potential function.

Ground State Quantum Weight: [2] $\sigma = 1$
Point Group: C_s
Bond Distances: B–Cl = [1.73] Å; B–F = [1.295] Å
Bond Angle: F–B–Cl = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [1.811033 \times 10^{-115}]\ g^3\ cm^6$

Enthalpy of Formation

The value of $\Delta_f H°(298.15\ K)$ for BClF(g) is estimated based on an assumption that $\Delta_f H° = 0$ for the reaction $BCl_2(g) + BF_2(g) = 2\ BClF(g)$. The values of $\Delta_f H°(298.15\ K)$ of $BCl_2(g)$ and $BF_2(g)$, used for calculation, are −20 and −130 $kcal·mol^{-1}$, respectively.

Heat Capacity and Entropy

The ground state quantum weight and bond angle are assumed to be the same as those for $BF_2(g)$. The bond distances of B–Cl and B–F are estimated by comparison with those in $BCl_3(g)$ and $BF_3(g)$ molecules, respectively. The vibrational frequencies were estimated from the corresponding values for $BCl_2(g)$ and $BF_2(g)$. The principal moments of inertia are: $I_A = 0.7794 \times 10^{-39}$, $I_B = 14.8586 \times 10^{-39}$, and $I_C = 15.6380 \times 10^{-39}$ g cm^2.

429(1)	608(1)

Ground State Quantum Weight: 1 $\sigma = 2$
Point Group: C_{2v}
Bond Distances: B–Cl = [1.73] Å; B–F = [1.295] Å
Bond Angles: F–B–Cl = [120]°; F–B–F = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [3.568886 \times 10^{-114}]\ g^3\cdot cm^6$

Enthalpy of Formation

The values for BCl_2F and $BClF_2$ of $\Delta_f H°(298.15\ K) = -154$ and $\Delta_f H°(298.15\ K) = -211.6\ kcal\cdot mol^{-1}$, respectively, are obtained from the average bond energies of BF_3 and BCl_3. The calculated values are each made less negative by about 0.8 $kcal\cdot mol^{-1}$ in order to make them consistent with the equilibrium measurements of Higgins, Leisegang, Raw and Rossow[2] and Gunn and Sanborn[2] for the reaction $BF_3(g) + BCl_3(g) \rightarrow BClF_2(g) + BCl_2F(g)$. Values for the heat of reaction are $\Delta_r H°(298.15\ K) = +1.68\ kcal\cdot mol^{-1}$ and $\Delta_r H°(298.15\ K) = 1.1$ (uncertainty of 0.5 to + 0.8) $kcal\cdot mol^{-1}$, the former calculated from the measured equilibrium constant and the statistical entropy change and the latter obtained from the variation of the equilibrium constant with temperature. Selection of $\Delta_r H°(298.15\ K) = 1.6\ kcal\cdot mol^{-1}$ fixes the sum of the enthalpy of formation of $BClF_2$ and BCl_2F as $-365.6\ kcal\cdot mol^{-1}$, but it does not determine the individual values. Thus, the selected enthalpies of formation are only as accurate as the average bond energy calculations on which they are based. A reasonable estimate of the uncertainty would be ± 5 $kcal\cdot mol^{-1}$.

Heat Capacity and Entropy

The observed frequencies of Lindeman and Wilson[3] were adjusted to the normal isotopic composition of 81.2% ^{10}B and 18.8% ^{11}B. The bond angles are assumed to be 120° and the bond lengths are taken to be the same as in the respective trihalides. The principal moments of inertia are: $I_A = 7.9360 \times 10^{-39}$, $I_B = 17.6063 \times 10^{-39}$, and $I_C = 25.5423 \times 10^{-39}\ g\cdot cm^2$.

Point Group: [$C_{\infty v}$]
Bond Distances: Cl–B = [1.75] Å; B–O = [1.20] Å
Bond Angle: Cl–B–O = [180]°
Rotational Constant: B_0 = [0.165056] cm^{-1}

Enthalpy of Formation

The vapor–phase equilibria existing in the $B_2O_3 + BCl_3$ system were determined by an effusion method in the temperature range 1234–1389 K by Blauer and Farber.[1] Based on the equilbrium constants reported for the reaction 1/3 B_2O_3(l) + 1/3 BCl_3(g) = BOCl(g), the 2nd and 3rd law values of $\Delta_f H°(298.15\ K)$ were evaluated as 57.7 and 56.3 $kcal·mol^{-1}$, respectively. The 3rd law value for $\Delta_f H°(298.15\ K)$ was adopted for the calculation of the enthalpy of formation, $\Delta_f H°$(BOCl, g, 298.15 K).

Heat Capacity and Entropy

The molecular structure is assumed to be linear. The vibrational frequencies are estimated from the values calculated by the valence force method described by Herzberg[2] using estimated force constants, $k_1 = 5.2 \times 10^5$, $k_2 = 16.7 \times 10^5$ dynes·cm^{-1} and $k_3 = 0.40 \times 10^{-11}$ dynes·cm·rad^{-1}. The B=O and B–Cl bond distances were assumed to be the same as those in BO(g) and BCl_3(g), respectively.

Enthalpy of Formation

Srivastava and Farber[1] have investigated the equilibrium vapors over the boron trichloride–boron system by mass spectrometry. Gaseous BCl_3 was allowed to flow into a boron nitride effusion cell which contained metallic boron. A flow variation study indicated that thermal equilibrium had been achieved during their experiments. Ion intensities for the species $BCl_3(g)$, $Bcl_2(g)$, and $BCl(g)$ were measured at electron energies slightly above appearance potentials in the temperature range 1513 to 1813 K. JANAF analysis of equiibrium constants for the reaction $BCl_3(g) + BCl(g) = 2BCl_2(g)$ which are obtained from their ion intenesity data yields a 3rd law $\Delta_r H$(298.15 K) value of 24.56 ± 1.00 kcal·mol^{-1} with a drift of −2.1 ± 2.0 cal·K^{-1}mol^{-1}. The 2nd law $\Delta_r H$ value at 298.15 K is 28.1 kcal·mol^{-1}. Using the 3rd law $\Delta_r H$ value in conjunction with JANAF enthalpies of formation [2] for $BCl_3(g)$ and BCl(g) and BCl(g), we calculate $\Delta_f H°(BCl_2, g, 298.15\ K) = -19.0 \pm 3.0$ kcal·mol^{-1}.

The only other reported data on the enthalpy of formation of BCl_2 comes from explosion studies carried out at elevated temperatures by Rusin and Tatevskii.[3] The BCl_2 radical was found to be stable at 2250 K in H_2–Cl_2–BCl_3 mixtures. These workers reported $\Delta_f H°(BCl_2, g, 298.15\ K) = -18.4 \pm 1.5$ kcal·mol^{-1} which confirms the results of Srivastava and Farber.[1]

We adopt $\Delta_f H°(BCl_2, g, 298.15\ K) = -19.0 \pm 3.0$ kcal·mol^{-1}. This value also leads to a realistic progression in the stepwise bond dissociation energies for BCl(g), BCl_2(g), and BCl_3(g). Using all JANAF data,[2] we calculate D_1(B–Cl) = 127.9, D_2(BCl–Cl) = 81.7, and D_3(BCl_2–Cl) = 106.2 kcal·mol^{-1}. This bond energy scheme, $D_1 > D_2 < D_3$, is consistent with that predicted for the Group III A fluorides by Hildenbrand.[4]

Heat Capacity and Entropy

The point group and the Cl–B–Cl bond angle are assumed to be the same as those for BF_2.[2] The B–Cl bond length is estimated to lie between those for BCl and BCl_3.[2] The principal moments of inertia are: $I_A = 1.4577 \times 10^{-39}$, $I_B = 24.2203 \times 10^{-39}$, and $I_C = 25.6780 \times 10^{-39}$ g·cm^2.

Dessaux *et al.*[5,6] observed a diffuse system of bands in the near ultraviolet which they attributed to the BCl_2 radical. The emission spectrum was obtained as chemiluminescence in the reaction between BCl_3 and atomic hydrogen. They indicated that the frequencies $\upsilon_1 = 470$, $\upsilon_2 = 240$, and $\upsilon_3 = 990\ cm^{-1}$ were consistent with their spectral data; however, alternate assignments are possible. We prefer the frequencies $\upsilon_1 = 700$, υ_2 250, and $\upsilon_3 = 725\ cm^{-1}$, since these values are more consistent with those for CCl_2, $SiCl_2$, and $AlCl_2$.[2]

By analogy with the isoelectronic molecule NO_2,[7] the ground state for BCl_2 is assumed to be $^2A_1$. Huckel–molecular–orbital calculations by Hastie and Margrave[8] suggest a doublet excited state ($^2B_1$) near 11,000 cm^{-1} which is included. The upper electronic levels are those observed by Dessaux *et al.*[6]

Enthalpy of Formation

The appearance potential of the positive ion fragment $BCl_2^+(g)$ from $BCl_3(g)$ was determined mass spectrometrically by Osberghaus,[1] Marriott,[2] and Koski[3] as 13.2 ± 0.5, 13.01 ± 0.02, and 11.8 ± 0.2 eV, respectively. From the reaction $BCl_3 + e^- = BCl_2^+ + Cl + 2e^-$, the corresponding values of $\Delta_f H°(298.15\ K)$ for $BCl_2^+(g)$ are derived to be 181.9 ± 11.5, 177.5 ± 0.5, and 149.6 ± 4.6 $kcal \cdot mol^{-1}$, using $\Delta_f H°(0\ K) = -96.078$ and 28.520 $kcal \cdot mol^{-1}$ for $BCl_3(g)$ and Cl(g). These electron impact values are superseded by the photoionization results of Dibeler and Walker[7] who report the onset of BCl_2^+ from BCl_3 as 12.30 ± 0.02 eV (283.65 ± 0.05 $kcal \cdot mol^{-1}$). This yields $\Delta_f H°(0\ K) = 159.05 \pm 0.6\ kcal \cdot mol^{-1}$ or $\Delta_f H°(298.15\ K) = 161.1 \pm 0.6\ kcal \cdot mol^{-1}$, which are adopted.

Heat Capacity and Entropy

The molecular structure is assumed to be linear using the Walsh[4] predictions for 16 valence electron XY_2 molecules. The electronic states, levels and vibrational frequencies are estimated by comparison with those for CO_2.[5] The B–Cl bond distance is estimated using the method of Krasnov.[6]

Bond Distances: B–Cl = [1.716] Å
Bond Angle: Cl–B–Cl = [100]°
Product of the Moments of Inertia: $I_A I_B I_C = [8.575781 \times 10^{-115}]\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation $\Delta_f H°(BCl_2^-, g, 0\ K) = -33.8 \pm 25\ kcal·mol^{-1}$, is obtained from an estimated electron affinity for BCl_2 and $\Delta_f H°(BCl_2, g, 0\ K) = -19.3 \pm 3.0\ kcal·mol^{-1}$.[1] Comparison of the ionization potentials and electron affinities for the isoelectronic molecules NO_2,[1,2] BF_2,[1] and AlF_2[1] indicates that in each case the difference between these two quantities (*IP–EA*) is roughly 7.1 eV. From this relationship, we estimate EA (BCl_2) = 0.63 ± 1.0 eV with IP (BCl_2) = 7.73 eV.[1]

Heat Capacity and Entropy

The correlation diagram of Walsh[3] predicts a bent configuration for BCl_2^- (18 valence electrons) with a bond angle considerably reduced from that for BCl_2. Based on the adopted angle for BCl_2 (112°),[1] we estimate the angle in BCl_2^- at 100°. Comparison with angles for CF_2 and SiF_2^+ indicates that the estimated angle is reasonable. The B–Cl bond length is taken equal to that for BCl.[1] The principal moments of inertia are: $I_A = 1.8951 \times 10^{-39}$, $I_B = 20.3463 \times 10^{-39}$, and $I_C = 22.2413 \times 10^{-39}\ g·cm^2$.

The ground state electronic configuration ($^1A_1$) and first excited singlet state ($^1B_1$) for BCl_2^- are estimated by analogy with those for CCl_2 and $SiCl_2$.[1] Also included is a triplet level at 12000 cm^{-1}. The energy separation (5000 cm^{-1}) of the $^3B_1$ and $^1B_1$ levels is estimated by comparison with the corresponding values for SO_2,[4] $SiCl_2$,[1] $GeCl_2$, and $SnCl_2$.[5] The vibrational frequencies are estimated from those for BCl_2, CCl_2, and $SiCl_2$.[1]

Ground State Quantum Weight: 1 $\sigma = 2$
Point Group: C_{2v}
Bond Distances: B–Cl = [1.73] Å; B–F = [1.295] Å
Bond Angles: Cl–B–Cl = [120]°; F–B–Cl = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = 1.202356 \times 10^{-113}\ g^3·cm^6$

Enthalpy of Formation

The values for BCl_2F and $BClF_2$ of $\Delta_f H°(298.15\ K) = -154$ and $\Delta_f H°(298.15\ K) = -211.6\ kcal·mol^{-1}$, respectively, are obtained from the average bond energies of BF_3 and BCl_3. The calculated values were each made less negative by about 0.8 $kcal·mol^{-1}$ in order to make them consistent with the equilibrium measurements of Higgins, Leisegang, Raw, and Rossouw,[1] and Gunn and Sanborn[2] for the reaction.

$$BF_3(g) + BCl_3(g) \rightarrow BClF_2(g) + BCl_2F(g).$$

Values for the enthalpy of reaction are $\Delta_r H(298.15\ K) = +1.68\ kcal·mol^{-1}$ and $\Delta_r H(298.15\ K) = 1.1$ (uncertainty of -0.5 to $+0.8$) $kcal·mol^{-1}$, the former calculated from the measured equilibrium constant and the statistical entropy change and the latter obtained from the variation of the equilibrium constant with temperature. Selection of $\Delta_r H(298.15\ K) = 1.6\ kcal·mol^{-1}$ fixes the sum of the enthalpies of formation of $BClF_2$ and BCl_2F as $-365.6\ kcal·mol^{-1}$, but it does not determine the individual values. Thus, the selected enthalpies of formation are only as accurate as the average bond energy calculations on which they are based. A reasonable estimate of the uncertainty would be $\pm 5\ kcal·mol^{-1}$.

Heat Capacity and Entropy

The spectroscopic constants are based on the work of Lindeman and Wilson,[3] who observed υ_1, υ_4, and υ_6 and calculated υ_2, υ_3, and υ_5. The frequencies were adjusted to the normal isotopic composition of 81.2% ^{11}B and 18.8% ^{10}B. The bond angles were taken to be 120° while the bond lengths were assumed to be the same as in the respective trihalides. The principal moments of inertia are $I_A = 11.8761 \times 10^{-39}$, $I_B = 26.4297 \times 10^{-39}$, and $I_C = 38.3059 \times 10^{-39}\ g·cm^2$.

Enthalpy of Formation

The chemical equilibria for the following two reactions: (A) $BCl_3(g) + H_2(g) = BHCl_2(g) + HCl(g)$, and (B) $6BHCl_2(g) = B_2H_6(g) + 4BCl_3(l, g)$ were investigated by Murib, Horvitz, and Bonecutter,[1] Mook, Seiler, and Watson[2] and Lynds and Bass.[3] Using the reported equilibrium constants, the corresponding enthalpy changes and the respective $\Delta_f H°(298.15\ K)$ values were evaluated. The results obtained are presented as follows.

Source	Reaction	T/K	$\Delta_f H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}
[1]	A	873 – 973	15.57 ± 0.8	16.19	−58.06 ± 0.5
[2]	A	1073 – 1273	13.50 ± 3.0	13.91	−60.3 ± 0.7
[1]	B	273	—	−17.85	−59.6
[3]	B	298	—	−19.09	−59.4

The value of $\Delta_f H°(298.15\ K)$ for $BHCl_2(g)$ is selected as − 59.3 ± 1 kcal·mol^{-1}.

Heat Capacity and Entropy

The molecular structure, B–H bond distance and Cl–B–Cl bond angle were obtained from Lynds and Bass.[4] The B–Cl bond distance was assumed to be the same as that in $BCl_3(g)$. The vibrational frequencies adopted were reported by Bass, Lynds, Wolfram, DeWames[5] and corrected to the average isotopic species. It has been pointed out that the complete assignment of the infrared spectra of $HBCl_2(g)$ is quite difficult due to the unavoidable presence of $BCl_3(g)$. The adopted frequencies were obtained using the Green's function and partitioning techniques, taking $HBCl_2$ as an "isotopic" species of BCl_3. An excellent agreement between the calculated and observed spectra reported Lynds and Bass[5] was claimed. Spectra of the mixture of BCl_3, $HBCl_2$ and $DBCl_2$ are quite complex and have been observed by Lynds and Stern,[6] Nadean and Oaks,[7] Mayers and Putnam[8] and only three bands were correlated with $HBCl_2$. Analysis of infrared data from previous works, according to the conventional Wilson's method of symmetry coordinates, has been undertaken by de Mandirola and Westerkamp.[9] Based on four observed frequencies, a set of six frequencies was derived and assigned. The principal moments of inertia are: $I_A = 1.7957 \times 10^{-39}$, $I_B = 26.9625 \times 10^{-39}$, and $I_C = 28.7581 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: 1 $\sigma = 6$
Point Group: D_{3h}
Bond Distance: B−Cl = 1.75 Å
Bond Angle: Cl−B−Cl = 120°
Product of the Moments of Inertia: $I_A I_B I_C = 3.956022 \times 10^{-113}\ g^3·cm^6$

Enthalpy of Formation

The enthalpy change of the reaction B(am) + 3/2 Cl_2(g) = BCl_3(g) has been determined in a calorimeter by Johnson, Miller and Prosen.[1] From the reported value $\Delta_r H°(298.15\ K) = -97.51 + 0.32\ kcal·mol^{-1}$, the enthalpy of formation for BCl_3(g) was derived as $-96.31 \pm 0.50\ kcal·mol^{-1}$, using $\Delta_f H°(298.15\ K) = 1.20 \pm 0.40\ kcal·mol^{-1}$ for the reaction B(cr) = B(am). Some other related enthalpies of reaction reported by previous investigators are presented as follows.

Source	Reaction	$\Delta_r H°(298.15\ K)$ kcal·mol^{-1}	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}
[2]	B(am) + 3/2 Cl_2(g) = BCl_3(g)	−97.4 ± 0.7	−96.2 ± 0.8
	B(am) + 3/2 Cl_2(g) = BCl_3(l)	−103.3 ± 0.6	−96.5 ± 0.7
[3]	B_2H_6(g) + 6 Cl_2(g) = 2 BCl_3(g) + 6 HCl(g)	−342.9	−100.4 ± 5.0
[4]	BCl_3(l) + (n+3)H_2O(l) = (H_3BO_3+3HCl)n H_2O (Sln)	−69.2 ± 1.0	−97.2 ± 1.0
[5]	BCl_3(l) + 2403 H_2O(l) = (H_3BO_3+3HCl)2400 H_2O (Sln)	−68.68 ± 0.06	−96.3 ± 0.2
[6]	BCl_3(l) + 593 H_2O(l) = (H_3BO_3+3HCl)590 H_2O (Sln)	−69.12 ± 0.11	−95.44 ± 0.39

The enthalpies of formation for BCl_3(l) derived from the enthalpies of hydrolysis reported by other investigatoars were reviewed by Johnson, Miller and Prosen.[1]

Heat Capacity and Entropy

The bond distance of B and Cl atoms has been reported to be 1.73 ± 0.02 and 1.76 ± 0.02, 1.75 Å by Levy and Brockway,[7] Gregg, Hampson and Jenkins, Jones, and Sutton,[8] and Spencer and Lipscomb,[9] respectively. The last value is adopted. The values of vibrational frequencies used were reported by Lindeman and Wilson.[10] The vibrational frequencies were also determined by Cassie,[11] Lassettre and Yost,[12] Scruby, Lacher and Park.[13] The molecular structure was given by Levy amd Brockway.[7] The principal moments of inertia are: $I_A = I_B = 27.0443 \times 10^{-39}$, and $I_C = 54.0887 \times 10^{-39}\ g·cm^2$.

Enthalpy of Formation

The equilibria of the reaction 2/3 B(cr) + 1/3 BF_3(g) = BF(g) were studied by Blauer, Greenbaum and Farber[1] by means of transpiratio at pressures below 300 μ. The values of log $K_p°$ at 1375 and 1476 K were reported as -3.99 ± 0.02 and -3.30 ± 0.05, respectively. By the 3rd law method the value of $\Delta_f H°$(298.15 K) for the reaction was derived to be 61.38 kcal·mol^{-1}, yielding $\Delta_f H°$(BF, g, 298.15 K) = -28.7 ± 2.6 kcal·mol^{-1}. The system B + CaF_2 was studied mass spectrometrically in a graphite Knudsen cell by Hildenbrand.[6] The equilibria involving BF(g) were observed. Intensity measurements were made at temperatures, 1583 1734 K. From the 3rd law value, $\Delta_f H°(298.15\ K) = 12.2 + 0.3$ kcal·mol^{-1}, for the reaction BF_3(g) + Ca(g) = BF(g) + CaF_2(g), the value of $\Delta_f H$d(298.15 K) for BF(g) was derived as -26.7 ± 2 kcal·mol^{-1}. The dissociation energy of BF(g) molecule has been reported by Herzberg,[2] Gaydon[3] and Barrow.[4] The corresponding values of $\Delta_f H°$(298.15 K) for BF(g) were derived. The results are compared with those obtained from equilibrium data as follows:

Source	Reaction	$\Delta_r H°$(298.15 K) kcal·mol^{-1}	$\Delta_f H°$(298.15 K) kcal·mol^{-1}
1	2/3 B(cr) + 1/3 BF_3(g) = BF(g)	61.38	-28.7 ± 2.6
2	BF(g) = B(g) + F(g)	100.2	+51.5
3	BF(g) = B(g) + F(g)	197.0	-45.3 ± 11.5
4	BF(g) = B(g) + F(g)	186.0	−34.3
5	2/3 B(cr) + 1/3 BF_3 = BF(g)	—	-28 ± 3
6	BF_3(g) + Ca(g) = BF(g) + CaF_2(g)	12.2	-26.7 ± 2

The value of $\Delta_f H°$(298.15 K) adopted is the average of the first and last $\Delta_f H°$(298.15 K) values listed in the above table.

Heat Capacity and Entropy

The spectroscopic constants used were obtained from Onaka[7] and to the average isotopic species. Spectroscopic constants for BF(g) were also reported by Herzberg.[2]

Enthalpy of Formation

The equilbrium constants for the reaction $B_2O_3(l) + BF_3(g) = 3\ BOF(g)$ in the temperature range 1054–1253 K were determined by Farber and Blauer[1] using the so-called Molecular Flow Reaction Method. The value of $\Delta_f H°$ for this reaction was evaluated by both the 2nd and 3rd law methods, using the equilibrium constants corrected for the trimer and correcting $K_p°$ at 1200 K from 9.6×10^{-11} to 9.6×10^{-10}. Hildebrand, Theard and Saul[2] analyzed the vapor above mixture of MgF_2 and B_2O_3 contained in a Knudsen cell with a mass spectrometer and found that in the temperature range 980–1230 K the vapor is composed of $BF_3(g)$, $(BOF)_3(g)$ and BOF(g) species. From the reported temperature dependence of appropriate ion intensities the enthalpy change of the reaction $(BOF)_3(g) = 3\ BOF(g)$ was derived by the 2nd law method as 127.9 $kcal·mol^{-1}$ at 1115 K or 129.75 $kcal·mol^{-1}$ at 298.15 K. The results obtained are presented as follows, using JANAF free energy functions and auxiliary data.

Source	Reaction	$\Delta_r H°(298.15\ K)$, $kcal·mol^{-1}$		$\Delta_f H°(298.15\ K)$ $kcal·mol^{-1}$
Farber and Blauer	$B_2O_3(l) + BF_3(g) = 3\ BOF(g)$	150.2 ± 16.6	149.0	−140.1 ± 6*
Hildenbrand *et al.*	$(BOF)_3(g) = 3\ BOF(g)$	129.8 ± 3	–	−145.2 ± 1.5

*Calculation based on the 3rd law value and one point rejected due to statistical test.

The adopted value of $\Delta_f H°(298.15\ K)$ for BOF(g) is the weighted average of the two values listed above.

Heat Capacity and Entropy

The molecular structure is assumed to be linear. The vibrational frequencies (υ) are estimated from the values calculated by the valence force method described by Herzberg[3] using estimated force constants, $k_1 = 10 \times 10^5$ dynes cm^{-1} and $k_2 = 0.47 \times 10^{-11}$ dynes cm rad^{-1}. The B=O and B–F bond distances are assumed to be the same as those in BO(g) and $BF_3(g)$ molecules.

Bond Angle: F–B–F = 112°
Product of Moments of Inertia: $I_A I_B I_C = [4.36647 \times 10^{-116}]\ g^3 \cdot cm^6$

Enthalpy of Formation

Srivastava and Farber,[1] using a gas inlet boron nitride effusion cell, performed a mass spectrometric study of the equilibrium vapor species over the system $BF_3(g) + B(cr)$. Ion intensities for $BF_3(g)$, BF(g) and $BF_2(g)$ were measured at ionizing electron energies slightly above appearance potentials (≈3 eV) in the temperature range 1477 to 1850 K and were used to obtain equilibrium data for the reaction $BF_3(g) + BF(g) = 2\ BF_2(g)$. We have analyzed their results and obtain $\Delta_r H°(298.15\ K) = 17.1 \pm 1.0\ kcal \cdot mol^{-1}$ from the 3rd law method with a drift of $-7.4 \pm 2.0\ cal \cdot K^{-1} \cdot mol^{-1}$ with JANAF heats of formation[2] for $BF_3(g)$ and BF(g).

Although no other experimental determinations of enthalpy of formation of BF_2 have been reported, Margrave[3] combined the appearance potential of BF_2^+ from BF_3 of 16.5 eV with an estimated ionization potential for BF_2 (IP = 9.4 ± 0.1 eV)[4] and calculated $\Delta_f H°(BF_2, g) \leq -124 \pm 9\ kcal \cdot mol^{-1}$. Based on the JANAF value for $AP(BF_2^+)$ of 15.81 eV.[2] we calculate $\Delta_f H°(BF_2, g, 0\ K) = -141.3\ kcal \cdot mol^{-1}$ by the same method. Margrave[3] also derived $\Delta_f H° = -135\ kcal \cdot mol^{-1}$ for BF_2 from average bond energy calculations and selected $\Delta_f H°(BF_2, g) = -130 \pm 6\ kcal \cdot mol^{-1}$ as the 'best' value. It is now apparent that this value is several kilocalories too positive.

We note that the adopted enthalpy of formation leads to a progression in the stepwise bond dissociation energies for BF(g), $BF_2(g)$ and $BF_3(g)$ which is consistent with the bond energy scheme predicted by Hildenbrand[5] for the Group III A fluorides, namely $D_1 > D_2 < D_3$. Using all JANAF data[2] we calculate bond dissociation energies of $D_1(B–F) = 179.4$, $D_2(BF–F) = 132.2$, and $D_3(BF_2–F) = 149.3\ kcal \cdot mol^{-1}$. The adopted value also corresponds to an ionization potential for BF_2 of $9.4 \pm 0.2\ eV^2$ which appears reasonable in comparison with IP's for other Group III A dihalides[6] and is the value estimated for BF_2 by Steele *et al.*[4]

Heat Capacity and Entropy

Nelson and Gordy[7] were successful in producing trapped BF_2 radicals by gamma irradiation of solid xenon which contained small concentrations of BF_3. From observations on the electron spin resonance spectra of these radicals, a bond angle of 112° for BF_2 was derived by these workers to account for the hybridization of the α bonding orbitals of the boron atom. We adopt their result and assume the B–F bond length to be the same as that for BHF_2.[2] The three principal moments of inertia are: $I_A = 0.7385 \times 10^{-39}$, $I_B = 7.3289 \times 10^{-39}$, and $I_C = 8.0674 \times 10^{-39}\ g \cdot cm^2$.

The ground state electronic configuration ($^2A_1$) and doublet excited state ($^2B_1$) are estimated by analogy with those for NO_2.[8] The vibrational frequencies are calculated from the stretching and bending force constants of $k = 4.82 \times 10^5$ and $k\delta/l^2 = 0.84 \times 10^5$ dynes/cm by the valence force method. These force constants are estimated from those for CF_2 and SiF_2.[2]

Enthalpy of Formation

The electron impact reaction at low pressure in BF_3(g) has been studied with a mass spectrometer by Osberghaus,[1] Law[2] and Marriott.[3] From the reported appearance potentials 17.0 ± 0.5, 16.2 ± 0.2, and 16.7 ± 0.05 eV and assumed process $BF_3 + e = BF_2^+ + F + 2\ e^-$, we calculate the corresponding values of $\Delta_f H°(BF_2^+, g, 298.15\ K)$ as 104.5 ± 11.5, 86.1 ± 4.6, and 85.4 ± 1.2 $kcal·mol^{-1}$, using $\Delta_f H°(0\ K) = -170.747$ and 18.357 $kcal·mol^{-1}$ for BF_3(g) and F(g). These electron impact values are superseded by the photoionization results of Dibeler and Liston[7] who report the onset of BF_2^+ from BF_3 as 15.81 eV (364.6 $kcal·mol^{-1}$). This yields $\Delta_f H°(0\ K) = 75.5 \pm 0.6\ kcal·mol^{-1}$ or $\Delta_f H°(298.15\ K) = 77.1 \pm 0.6\ kcal·mol^{-1}$, which are adopted.

Heat Capacity and Entropy

The molecular structure is assumed to be linear using the Walsh[4] prediction for 16 valence electron XY_2 molecules. The electronic states, levels, and vibrational frequencies are estimated by comparison with those for CO_2.[5] The B–F bond distances is calculated by the method recommended by Krasnov.[5]

Enthalpy of Formation

The BF_2 ion has been detected mass spectrometrically by MacNeil and Thynne[1] and Farber *et al.*[2] MacNeil and Thynne[1] reported the formation of the negative ion at electron energies of approximately 7.6 eV as a result of electron bombardment of BF_3(g). Assuming the ionization process to be $BF_3(g) + e = BF_2\ (g) + F(g)$, we calculate $\Delta_f H°(BF_2\ ,\ g,\ 0\ K) = -113.8\ kcal \cdot mol^{-1}$ from their results with JANAF enthalpies of formation[3] for BF_3(g) and F(g). This value leads to an unrealistic electron affinity (EA) for BF_2 of −1.1 eV. It seems most likely that the BF_2^- ion was formed in the dissociative ionization of BF_3(g) with considerable excess energy.

Farber, *et al.*[2] observed the formation of the BF_2^- ion in a molecular flow effusion mass spectrometric study of the $BF_3(g) + KF(g) + B(cr)$ system. Equilibrium data for the electron transfer reaction $BF_2\ (g) + F(g) = BF_2(g) + F\ (g)$ were reported for the temperature range 1253 to 1640 K. We have analyzed their results with JANAF functions and obtain $\Delta_f H°(298.15\ K) = -26.3 \pm 1.8\ kcal \cdot mol^{-1}$ by the 3rd law method with a drift of $-1.5 \pm 3.1\ cal \cdot K^{-1} \cdot mol^{-1}$, the 2nd law $\Delta_r H°(298.15\ K)$ value is $-24.2\ kcal \cdot mol^{-1}$. We adopt the 3rd law value and calculate $\Delta_f H°(BF_2\ ,\ g,\ 298.15\ K) = -191.7 \pm 8.0\ kcal \cdot mol^{-1}$ with JANAF auxiliary data. The adopted enthalpy of formation leads to EA $(BF_2) = 2.14 \pm 0.5$ eV.

Heat Capacity and Entropy

The correlation diagram of Walsh[4] predicts a bent configuration for BF_2^- (18 valence electrons) with a bond angle considerably reduced from that for BF_2(112°).[3] These predictions are supported by the experimentally determined bond angles for the isoelectronic molecules CF_2(104.9°),[3] SiF_2(101°)[3] and GeF_2(94°).[5] Thus we adopt a bond angle for BF_2^- of 100° and assume the B–F bond length to be the same as that for BF.[3] The principal moments of inertia are: $I_A = 0.9240 \times 10^{-39}$, $I_B = 5.9251 \times 10^{-39}$, and $I_C = 6.8491 \times 10^{-39}\ g \cdot cm^2$.

The electronic states, levels, and quantum weights are estimated by analogy with those for CF_2.[3] The vibrational frequencies are calculated form the stretching and bending force constants of $k = 5.16 \times 10^5$ and $k\delta/l^2 = 0.91 \times 10^5$ dynes/cn by the valence force method. These force constants are estimated by comparison with those for CF_2, SiF_2, and BF_2.[3]

Bond Angles: F–B–F = 120 ± 5°; F–B–H = 120 ± 2.5°
Product of the Moments of Inertia: $I_A I_B I_C = 7.51811 \times 10^{-116}\ g^3·cm^6$

Enthalpy of Formation

The equilibrium pressures at 296 and 360 K for the reaction 1/6 B_2H_6(g) + 2/3 BF_3(g) = HBF_2(g) were determined by Porter and Wason.[1] By the 3rd law method, the enthalpy change was evaluated to be 3.06 ± 0.33 kcal·mol^{-1}. Based on the values of $\Delta_f H°(298.15\ K)$ for B_2H_6(g) and BF_3(g) as 9.8 and −270.1 kcal·mol^{-1}, respectively, the enthalpy of formation for BHF_2(g) was derived to be −175.4 ± 0.8 kcal·mol^{-1}. The drift in the 3rd law enthalpy of reaction is 3.6 cal·K^{-1}·mol^{-1}.

Heat Capacity and Entropy

The infrared spectrum of BHF_2(g) has been observed by Coyle *et al.*,[2] Ritter, and Farrar,[2] Perec and Becks,[3] Lynds,[4] and Porter and Wason.[1]

The vibrational frequencies, except υ_5, were obtained form Porter and Wason[1] and corrected to the average isotopic species. The value of υ_5 was estimated by comparison with the same value reported by other investigators. The molecular structure, bond distances and angles were obtained from Perec and Becks.[3] The principal moments of inertia are: $I_A = 1.0402 \times 10^{-39}$, $I_B = 7.9974 \times 10^{-39}$, and $I_C = 9.0376 \times 10^{-39}$ g·cm^2.

The vibrational rotational spectrum of BHF_2(g) has been studied by Lynds and Bass.[5] The values of υ_1, υ_2, υ_3, and υ_6 were assigned as 1164.2, 2620.8, 541.5 and 923.5 cm^{-1}, respectively, which are in fair agreement with the adopted values reported by Porter and Wason.[1]

Ground State Quantum Weight: 1 $\sigma = 1$

Point Group: C_s

Bond Distances: B–F = *[1.30]* Å; B–O = *[1.36]* Å; O–H = *[0.96]* Å

Bond Angles: F–B–F = [120]°; F–B–O = [120]°; B–O–H = [105]°

Product of the Moments of Inertia: $I_A I_B I_C = [1.051510 \times 10^{-114}]\ g^3·cm^6$

Enthalpy of Formation

The value of enthalpy of formation, $\Delta_f H°(298.15\ K)$, was calculated based on an assumption that $\Delta_f H°(298.15\ K) = 0$ for the reaction 2/3 $BF_3(g)$ + 1/3 $B(OH)_3(g)$ = $BOHF_2(g)$.

Heat Capacity and Entropy

The vibrational frequencies were obtained from Gordon.[1] The B–F and O–H bond distances were assumed to be the same as those in $BF_3(g)$ and $H_2O(g)$ molecules, respectively. The B–O bond distance and the bond angles were estimated from related molecules. The principal moments of inertia are: $I_A = 7.8128 \times 10^{-39}$, $I_B = 8.3349 \times 10^{-39}$, and $I_C = 16.1476 \times 10^{-39}\ g·cm^2$.

Bond Distances: B–F = 1.30 ± 0.05 Å; B–O = 1.40 ± 0.05 Å
Bond Angles: F–B–O = 117 ± 5°; F–B–F = 126 ± 5°
Product of the Moments of Inertia: $I_A I_B I_C = 9.948921 \times 10^{-115}\ g^3·cm^6$

Enthalpy of Formation

The molecule BF_2O(g) is similar to BO_2(g) in that both have an extra electron. Based on an assumption that $D_0°(F_2B–O) = D_0°(OB–O) – 10 = 134.3$ kcal·mol^{-1} where the quantity −10 kcal·mol^{-1} is estimated as the resonance stabilization energy in BO_2(g), $\Delta_f H°(F_2BO, g, 298.15\ K)$ is calculated to be −206 kcal·mol^{-1}.

Assuming $D_0°(F_2BO–H) = D_0°(HO–H) = 118$ kcal·mol^{-1}, the value of $\Delta_f H°(F_2BO, g, 298.15\ K)$ is evaluated as −191.6 kcal·mol^{-1}, using $\Delta_f H°(0\ K) = 51.63$ and −257.35 kcal·mol^{-1} for H(g) and F_2BOH(g), respectively.

The value of $\Delta_f H°(F_2BO, g, 298.15\ K)$ is tentatively adopted as −200 ± 15 kcal·mol^{-1}

Heat Capacity and Entropy

The 4465–A emission spectrum was observed in a discharge through BF_3 and O_2 by Mathews.[1] The emitter of the discharge was shown to be either the planar BOF_2 molecule or molecule–ion BOF_2^+. No experimental evidence has been found to distinguish between them. The molecular structure, bond distances and angles were reported by Mathews,[1] based on a rotational analysis of the emission spectrum. These values are adopted here.

Three vibrational frequencies for both $^{11}B^{16}OF_2$ and $^{10}B^{16}OF_2$ molecules (or ions) were deermined by vibrational analysis of the 5800–Å bands of the emission spectrum by Mathews and Innes.[2] These values are corrected to the average isotopic species and adopted. The last three frequencies are estimated from values calculated by the valence–force method, using force constants transferred from COF_2(g).

The ground state quantum weight is taken as 2 because of the extra electron. The other two electronic levels are estimated from the band systems at 5800 and 4465 Å, assuming that two systems have a common lower state, i.e. the ground state.

The principal moments of inertia are: $I_A = 7.4051 \times 10^{-39}$, $I_B = 8.4655 \times 10^{-39}$, and $I_C = 15.8706 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: 1 $\sigma = 6$

Point Group: D_{3h}

Bond Distance: B–F = 1.307 ± 0.002 Å

Bond Angle: F–B–F = 120°

Products of the Moments of Inertia: $I_A I_B I_C = 1.056517 \times 10^{-114}\ g^3 \cdot cm^6$

Enthalpy of Formation

The adopted enthalpy of formation was selected by a simultaneous adjustment of several interrelated pieces of data relating to the heat of formation of HF (see HF, g table 12–31–68). The data which were considered relating directly to BF_3 were as follows:

A. $NF_3(g) + B(cr, \beta) \rightarrow BF_3(g) + 0.5\ N_2$ and $\Delta_f H°(298.15\ K) = 239.46 \pm 1.2\ kcal \cdot mol^{-1}$.

Ludwig and Cooper[1] report the above value after corretion for 0.44 percent impurities in the boron. As much as 5 percent unburned boron was determined by analysis.

B. $1.5\ F_2(g) + B(cr, \beta) \rightarrow BF_3(g)$

Wise *et al.*[2] originally reported $\Delta_f H°(298.15\ K) = -270.1 \pm 0.24\ kcal \cdot mol^{-1}$ but later reanalysis [3] of the impurities and due allowance for their effect changed this to $-271.6 \pm 0.9\ kcal \cdot mol^{-1}$. Johnson *et al.*[3] using zone refined boron obtained $\Delta_f H°(298.15\ K) = -271.65 \pm 0.22\ kcal \cdot mol^{-1}$ after correction for 0.12 percent impurities. Domalski and Armstrong[4] obtained $\Delta_f H°(298.15\ K) = -271.03 \pm 0.51\ kcal \cdot mol^{-1}$ from a combustion in the presence of Teflon, the boron contained 0.32 percent impurities and corrections were included. The above reaction constituted about 0.35 of the total energy measured. The measurements of Gross *et al.*,[5] although on a zone refined sample, did not include a complete purity analysis and their data were not included since probable impurities could introduce serious errors.

C. $3\ HF(50\ H_2O) + B(cr, \beta) + 0.75\ O_2(g) \rightarrow BF_3(g) + 1.5\ H_2O(l)$

From the measurements of Gunn[6] on the reaction of $BF_3(g) + 15.67\ HF(3.747\ H_2O) \rightarrow$ [solution] and Good and Mansson[7] for the reaction $B(cr, \beta) + 0.75\ O_2(g) + 18.57\ HF(3.065\ H_2O) \rightarrow$ [solution] $+ 1.5\ H_2O(l)$, where the resulting solutions have the same composition, we obtain $\Delta_f H°(298.15\ K) = -142.77 \pm 0.5\ kcal \cdot mol^{-1}$. Further details of the simultaneous solution are given by Syverud.[8]

Heat Capacity and Entropy

The fundamental frequencies were selected from the measurements of Lindeman and Wilson,[9] McKean,[10] Nielsen,[11] Anderson *et al.*[12] and Yost *et al.*[13] The bond length and structure of those reported by Gin *et al.*[14] which are in agreement with those of Kuchitsu and Konaka[15] from gas phase electron diffraction. These measurements disagree with the earlier determinations of Nielsen[11] and Levy and Brockway[16] but are considerably more precise and are adopted.

The principal moments of inertia are $I_A = I_B = 8.0838 \times 10^{-39}$, and $I_C = 16.1676 \times 10^{-39}\ g \cdot cm^2$.

PREVIOUS: June 1969 (1 atm) CURRENT: June 1969 (1 bar)

$S°(298.15\ K) = 133.89 \pm 4.0\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{trs} = 556\ K$
$T_{fus} = 843\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -1887 \pm 4\ kJ \cdot mol^{-1}$
$\Delta_{trs} H° = 14.06 \pm 0.16\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 17.66 \pm 0.16\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Bills and Cotton[1] measured the enthalpies of several reactions at 25°C which led to the following result:

$H_3BO_3(cr) + 4(HF23\ H_2O) + KNO_3(cr) \rightarrow KBF_4(cr) + HNO_3 92\ H_2O + 3\ H_2O$.

Combining this result with the following enthalpy of formation data,

$\Delta_f H°(H_3BO_3, cr) = -261.47 \pm 0.2$ kcal·mol^{-1} [2]
$\Delta_f H°(HF23\ H_2O) = -76.75 \pm 0.1$ kcal·mol^{-1} [3]
$\Delta_f H°(KNO_3, cr) = -118.22$ kcal·mol^{-1} [4]
$\Delta_f H°(HNO_3 92\ H_2O) = -49.44$ kcal·mol^{-1} [5]
$\Delta_f H°(H_2O, l) = -68.315$ kcal·mol^{-1}

We derive, $\Delta_f H°(KBF_4, cr) = -451.6 \pm 1.2$ kcal·mol^{-1}.

Gross, Hayman and Joel[6] recently measured the following enthalpies of reaction:

$NaF(cr) + BF_3(g) \rightarrow NaBF_4(cr)$ $\Delta_r H° = -32.04 \pm 0.12$ kcal·mol^{-1}
$[KBF_4 + NaF](cr) + HF(aq) \rightarrow$ Soln A $\Delta_{sol} H° = +8.14 \pm 0.18$ kcal·mol^{-1}
$[NaBF_4 + KF](cr) + HF(aq) \rightarrow$ Soln A $\Delta_{sol} H° = -2.94 \pm 0.13$ kcal·mol^{-1}

These data combine to give $\Delta H_r = -43.13 \pm 0.22$ kcal·mol^{-1} for the reaction $KF(cr) + BF_3(g) \rightarrow KBF_4(cr)$. Combining this result with the following enthalpies of formation: $\Delta_f H°(KF, cr) = -135.9 \pm 0.1$ kcal·mol^{-1};[7] $\Delta_f H°(BF_3, g) = -271.42 \pm 0.4$ kcal·mol^{-1},[7] we derive $\Delta_f H°(KBF_4, cr) = -450.5 \pm 0.7$ kcal·mol^{-1}. An average value, $\Delta_f H°(KBF_4, cr) = -451.0 \pm 1$ kcal·mol^{-1}, of these two results is adopted here.

Heat Capacity and Entropy

The heat capacity data are calculated from the high temperature enthalpy data of Dworkin and Bredig.[8] $S°(298.15\ K)$ is chosen such that a 3rd law analysis of the equilibrium data for the reaction $KBF_4(cr, l) = KF(cr, l) + BF_3(g)$ reported by de Boer and van Liempt[9] gives the experimentally determined heat of reaction at 25°C.[6]

Transition Data

T_{trs} is from the high temperature studies of Dworkin and Bredig.[8] $\Delta_{trs} H°$ is calcualted from their high temperature enthalpy data.

Fusion Data

T_{fus} has been reported as 803 K by de Boer and van Liempt[9] and 843 K by Dworkin and Bredig.[8] Dworkin and Bredig's value is adopted here. $\Delta_{fus} H°$ is calculated from their high temperature enthalpy data.

Sublimation Data

$\Delta_{sub} H°(298.15\ K)$ is estimated by comparison with data for $LiALF_4(cr)$ reported by Hildenbrand and Theard.[10]

Potassium Tetraflouroborate (KBF_4) LIQUID M_r = 125.901912

$S°(298.15\ K) = [150.129]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 843\ K$

$\Delta_f H°(0\ K) = Unknown$
$\Delta_f H°(298.15\ K) = [-1869.415]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 17.66 \pm 0.16\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$(l, 298.15 K) is calculated from $\Delta_f H°$(cr) by adding $\Delta_{fus} H°$ and the difference in enthalpy, $H°(843\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The heat capacity data are calculated from the high temperature enthalpy data of Dworkin and Bredig.[1] $S°(298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

T_{fus} has been reported as 803 K by de Boer and van Liempt[2] and 843 K by Dworkin and Bredig.[1] Dworkin and Bredig's value is adopted here. $\Delta_{fus} H°$ is calculated from their high temperature enthalpy data.

Ground State Quantum Weight: [1] α = [3]
Point Group: $[C_{3v}]$
Bond Distances: B-F = 1.380 Å; K-F = 2.752 Å; B-K = [2.863] Å
Bond Angles: F-B-F = 109°28'; F_{ax}-B-K = [180]°
Product of Moments of Inertia: $I_A I_B I_C = [4.547923 \times 10^{-113}]\ g^3 \cdot cm^6$

Enthalpy of Formation

$\Delta_f H$(g) is calculated from Δ_fH(cr) and the estimated enthalpy of sublimation.

Heat Capacity and Entropy

The vibrational frequencies are estimated by comparison with data for BF_4^-, BF_3, KF, and K_2F_2. The infrared and Raman spectra of BF_4^- in various phases have been reported by.[1-4] The molecular structure is assumed to be the same as for $LiAlF_4$ as discussed by Porter and Zeller.[5] The B–F and K–F bond lengths and F–B–F bond angle are average values of the crystallographic data recently reported by Clark and Lynton.[6] The B–K bond length is calcualted from the above structural data according to the assumed molecular model. The principal moments of inertia are $I_A = I_B = 16.0214 \times 10^{-39}$, and $I_B = I_C = 53.2791 \times 10^{-39}\ g \cdot cm^2$.

ω_e = [2368] cm^{-1} $\omega_e x_e$ = [49] cm^{-1} σ = 1
B_e = 12.036 cm^{-1} α_e = 0.413 cm^{-1} r_e = 1.2325 Å

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ was calculated from $D_0°(BH) \approx 3.39 \pm 0.04$ e.v. reported by Hurley.[1] Hurley stated "by combining an analysis of the spectroscopic data with theoretical calculations, we obtain a greatly improved estimate of $D_0°(BH)$". This value and the other $D_0°(BH)$ values which are tabulated below are based on the same spectroscopic data but differ due to different methods of analysis.

$D_0°(BH)$, eV	Method	Source
3.0 ± 0.4	Birge Sponer extrapolations	(2)
3.6	Observed predissociation by rotation in BH, A'Π and deduced $D_0°(BH)$	(3)
<3.51	Pre dissociation limit. This is only an upper limit due to a maximum in the potential curve of the A'Π state	(4)
3.38 ± 0.04	The potential energy curve of the A'Π state was determined and was found to have a maximum and a minimum in agreement with Herzberg and Mundie	The selected $D_0°(BH)$ value as reported by Hurley (1).

Heat Capacity and Entropy

The molecular constants from Herzberg[4] were adjusted for the natural abundance of ^{10}B and ^{11}B. Because the constants ω_e and $\omega_e x_e$ could not be determined directly from the spectrum, Almy and Horsfall[3] obtained estimates for the ground state $X\ ^1\Sigma^+$ from the rotational constants for this state and the relations $D_e = 4B_e^3/\omega_e^2$ and $\omega_e x_e/\omega_e = 0.6\ \alpha_e/B_e$.

Enthalpy of Formation

We calculate $\Delta_f H°$ from a selected value, $\Delta_f H°$(DBO, g) = −47.95 kcal·mol^{-1}, by combining this value with zero-point energies and relative enthalpies, $H°(298.15\ K)-E_0°$, for HBO, D_2, DBO and H_2. All ancillary data are from JANAF[1] unless otherwise indicated. The zero-point energies are estimated as one-half the sum of the vibrational frequencies. The vibrational frequencies for DBO are taken from the matrix-isolation results of Lory and Porter.[2] We assume that DBO and HBO have similar structures, and we calculate the relative enthalpy for DBO as $H°(298.15\ K)-E_0° = -2.27$ kcal·mol^{-1}. Data for D_2 are taken from NBS.[3]

The selected value of $\Delta_f H°$ for DBO is obtained from the results of a mass-spectrometric study[4,5] of the reaction of D (g) with B_2O_3(l). The thermal results which were initially reported[4] for a study of the reactions (A) $D_2(g) + B_2O_3(l) = DBO(g) + DOBO(g)$ and (B) $D_2O(g) + B_2O_3(l) = 2DOBO(g)$ are unreliable due to erroneous equilibrium constants. 2nd-law enthalpies for these two reactions have been reported in revised form in a later publication.[5] Apparently, no attempt was made in this study to perform calibration experiments which would have allowed the ion intensity data to be converted to absolute partial pressures; thus, precluding a 3rd law analysis. We combine their 2nd law values[5] for $\Delta_r H$ (1296 K) for reactions (A) and (B) to give $\Delta_r H(1296\ K) = 135 \pm 4$ kcal·mol^{-1} for the process $2D_2(g) + B_2O_3(l) = 2DBO(g) + D_2O(g)$. Corrected to 298.15 K this value is 144.1 kcal·mol^{-1} which leads to $\Delta_f H°$(DBO,g, 298.15 K) = −47.95 ± 2.3 kcal·mol^{-1} with $\Delta_f H°(D_2O, g, 298.15\ K) = -59.561 \pm 0.02$ kcal·mol^{-1}[13] and $\Delta_f H°(B_2O_3, l, 298.15\ K) = 299.56 \pm 0.6$ kcal·mol^{-1}.[1]

Comparison of values for the stretching force constants in HBO, BH_3,[6] BO, and B_2O_2[1] suggests a similarity in the bonds of these molecules. Using $D_0°(298.15\ K)$ (H–B) = $D°(298.15\ K)$ (BH_3) = 87.9 kcal·mol^{-1} and $D_0°(298.15\ K)$ (B=O) = $D_0°(298.15\ K)$ (BO) + $D_0°(298.15\ K)$ (B_2O_2) /2 = 202 kcal·mol^{-1},[1] we calculate an enthalpy of atomization for HBO of 298.9 kcal·mol. This corresponds to $\Delta_f H°$(HBO, g, 298.15 K) = −45.4 kcal·mol^{-1} which lends support to the experimental measurements at Farber *et al.*[4,5] Pervious JANAF estimates[7] of $\Delta_f H°$ via bond energy calculations led to results which were too positive due to the use of an inaccurate value (168 kcal·mol^{-1}) for $D_0°$ (B=O). A recent ab-initio LCAO-MO-SCF investigation[8] of HBO yields $\Delta_{at}H$ = 232.2 kcal·mol^{-1}; however, this value does not include a contribution from correlation effects[9,16] and therefore is too low.

Heat Capacity and Entropy

The B=O stretching $(\upsilon)_3$ and bending $(\upsilon)_2$ frequencies for the isotopes $H^{11}BO$ and $H^{10}BO$ have been measured in a low-temperature argon matrix.[2] These values are corrected for the natural isotopic abundances of boron. The H–B stretching frequency $(\upsilon)_1$ is calculated from an estimated force constant by the valence force method.[10] The stretching force constant K_1 is estimated from the ratio $K_1/K_D/l_1l_2$ = 17.47 which is the value we calculate for DBO from the measured frequencies of Lory and Porter.[2] These workers[2] used a slightly different value for K_1 and obtained a value for υ_1 which is roughly 50 cm^{-1} higher than our result. We believe our estimate is probably more nearly correct, since it agrees much better with the H–B stretching frequency (2808 cm^{-1}) observed for BH_3.[6] MO calculations show that the pattern of valence orbitals for HBO is similar to that in HCN[8] and HCP.[11,16] The ordering is substantiated by the photoelectron spectra[12] which have been observed for HCN and HCP. This suggests that the ground and excited electronic states for these isoelectronic molecules are quite similar. We assume that the ground state configuration is $^1\Sigma^+$ by analogy with those for HCN and HCP.[1] We also include three triplet levels which are estimated from those observed for HCP[1] and predicted for HCN.[13]

Enthalpy of Formation

The HBO⁺ ion has been detected mass spectrometrically by Sholette and Porter[1] *and Farber and Frisch.*[2] However, no appearance potential data have been reported for the ion. Kroto *et al.*[3] recently attempted to measure the photelectron spectrum of HBO by passing water vapor over heated boron. The spectrum showed no bands which could be definitely assigned to HBO monomer. Unfortunately, the region of their spectrum (~14–15 eV) where the first photoelectron band of HBO would be expected to lie shows a broad band which also appeared in the spectrum of HBS above 1150°C. Kroto *et al.*[4] have assigned this band to diborane. We believe the HBO band may well be hidden under this broad band.

We employ Koopmans' theorem[4] to obtain the ionization potential of HBO as 14.3 eV from the one electron orbital energies reported by Thomson and Wishart.[5] A comparison of Koopmans' theorem IP's for the related species HBS,[6] HCN,[5] and HCP[7] with experimental values[8,9] shows that the theoretical calculations correctly predict these ionization potentials to within about ± 0.4 eV. We adopt $\Delta_f H° = 329.7_6 \pm 9$ $kcal \cdot mol^{-1}$ for the ionization process $HBO(g) + e^- = HBO^+(g) + 2e^-$ at 0 K, and we obtain $\Delta_f H°(HBO^+, g, 0\ K) = 282.6 \pm 12.0\ kcal \cdot mol^{-1}$ when the former value is combined with $\Delta_f H°(HBO, g, 0\ K) = -47.2 \pm 3.0\ kcal \cdot mol^{-1}$[18]. $\Delta_f H°(298.15\ K)$ is 283.8 ± 12.0 $kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

Extensive ab initio MO calculations[5] reported for HBO show that the highest occupied orbital is of Π–symmetry and is localized mainly on the oxygen atom. The Walsh diagram[10] for HAB molecules predicts that this orbital is bonding. We would expect therefore that the ion is less strongly bound than the parent molecule. For HCN which has the same orbital ordering as HBO,[5] ionization[11] occurs with a 2.2% increase in the H–C bond length and a 4.7% increase in the C≡N bond length. We assume a similar increase in the bond lengths of HBO[8] upon loss of the bonding electron. A linear configuration is assumed by analogy with that for HBS^+.[8] This assumption is supported by predictions from the Walsh diagram.[10]

All vibrational frequencies are calculated from estimated force constants by a valence force method.[12] The force constants are estimated from those for HBO[8] by comparison with the changes in the changes in the force constants for HCN[8] produced on ionization.[9] The electronic states and levels are estimated from those observed for isoelectronic ions HBS^+, and HCP^+.[9] We estimate the uncertainties in our calculated frequencies as ±50 cm^{-1} which introduces an error of only about ±0.1 $cal \cdot K^{-1} \cdot mol^{-1}$ in the value of $S°(298.15\ K)$. The uncertainty in the *electronic levels contribute the majority of the error in the entropy.* We predict that the energy separation of the $^2\Pi$–$^2\Sigma$ states is small. Thus, it is possible that the ground state is $^2\Sigma$ as is the case for the isoelectronic ions CO^+ and N_2^+.[13] If the ground state is $^2\Sigma$, then our entropies should be decreased by roughly 1.5 gibbs/mol at all temperatures above 298.15 K. The enthalpy is much more certain than the entropy. Below 2000 K the uncertainty in our relative enthalpies probably does not exceed a few calories. The uncertainty increases at higher temperatures and is about 1.0 $kcal \cdot mol^{-1}$ at 4000 K. All excited states are expected to be linear as observed for HBS^+.[3]

Enthalpy of Formation

The identification of the HBO^- radical has been made from observations of its electron spin resonance spectra which was measured[1,2] in γ–irradiated polycrystalline potassium borohydride. This assignment is confirmed by the fact that hyperfine coupling constants calculated by INDO[3] and UHF[4,5] methods are in reasonable agreement with the spectral data.[2] No experimental measurement of the electron affinity (EA) has been reported: however, recent MO calculations[6] predict that the value is small. We note that these calculations predict incorrectly the relative stabilities of HBO and HBO^- and therefore are of no use in the establishment of the absolute value of EA. This inversion in the predicted stabilities of the radical and parent molecule most likely arises from the neglect of correlation effects.

We estimate $\Delta_f H°$ from a consideration of bond–energy schemes. For the dissociative process $HBO^-(g) = H(g) + B(g) + O^-(g)$, we assume $\Delta_{at}H°(HBO,g,\ 0\ K) = 289.4\ kcal \cdot mol^{-1}$.[7] This atomization energy gives $\Delta_f H°(HBO^-,\ g,\ 0\ K) \approx -81.0\ kcal \cdot mol^{-1}$ which we believe is an upper limit since the unpaired electron in HBO^- is antibonding[8] and consequently, one would expect $\Delta_{at}H°(HBO^-) < \Delta_{at}H°(HBO)$. A lower limit of $\Delta_f H°$ can be obtained from a consideration of the H–B bond dissociation energy. It is very unlikely that $D_0°(H–BO^-) < D_0°(H–CO)$ which is equal to 14.1 $kcal \cdot mol^{-1}$. Using this value for $D_0°(H–BO^-)$, we obtain $\Delta_f H°(HBO^-,\ g,\ 0\ K) = -33\ kcal \cdot mol^{-1}$ with $\Delta_f H°(H,g,\ 0\ K) = 52.103\ kcal \cdot mol^{-1}$ [7] and $\Delta_f H°(BO^-,\ g,\ 0\ K) = -71.0\ kcal \cdot mol^{-1}$.[9] We adopt an average ($-57 \pm 24\ kcal \cdot mol^{-1}$) of the upper and lower limit values. Our adopted $\Delta_f H°$ value corresponds to an EA(HBO^-) of 0.42 ± 1.0 eV.

Heat Capacity and Entropy

The bond lengths are those reported by Thomson[3] who performed an INDO calculation in which the bond lengths were determined by minimization of the total energy. The esr spectrum[1,2] of HBO^- is consistent with a bent structure. Catton *et al.*[2] obtained bond angles of 121° and 125° from the p:s ratios deduced from estimated and observed anisotropic components of the hyperfine tensors. A similar calculation[2] for HCO and HCN^- led to bond angles which agreed with independent values to within ±5°. We adopt a bond angle of 123 ± 5°. MO calculations[3] give an angle of 129°. However, the energy minimization procedure with the INDO method generally over–estimates the angle as evidenced by the results for HCO[10] and HCN.[2,3] The principal moments of inertia are: $I_A = 0.1484 \times 10^{-39}$, $I_B = 2.4017 \times 10^{-39}$, and $I_C = 2.5501 \times 10^{-39}\ g \cdot cm^2$.

The electronic levels and quantum weights are taken from those for HCO,[7] which is isoelectronic with HBO^-. The vibrational frequencies arae estimated by comparison with the corresponding values for HBO, HBO^+, HCO and HCO^+.[7]

$S°(298.15\ K) = [48.95 \pm 4.2]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 509 \pm 1\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -802.8 \pm 0.84\ kJ·mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

The enthalpy change ($\Delta_r H°$) of the reaction HBO_2(cr, I) + H_2O(l) = H_3BO_3(cr) has been determined Kilday.[1] From the value, $\Delta_r H°(298.15\ K) = -1.28\ kcal·mol^{-1}$, the enthalpy of formation $\Delta_f H°(298.15\ K)$ for HBO_2 (cr, I) is derived to be $-191.87 \pm 0.20\ kcal·mol^{-1}$ which is adopted. The enthalpies of solution of HBO_2 (cr, I) in H_2O(l) were measured by Sokolova, *et al.*[2] Based on the reported value, $\Delta_r H°(298.15\ K) = 1.76 \pm 0.01\ kcal·mol^{-1}$ for the reaction HBO_2(cr, I) + 501 H_2O(l) = H_3BO_3·500 H_2O(Sol), the enthalpy of formation for HBO_2(cr, I) was derived as $-189.46 \pm 0.20\ kcal·mol^{-1}$, using $\Delta_f H°$(H_2O, l, 298.15 K) = −68.317 and $\Delta_f H°$(H_3BO_3·500 H_2O, Sol, 298.15 K), ≈ $-256.02 \pm 0.20\ kcal·mol^{-1}$.

Heat Capacity and Entropy

The values of heat capacity for HBO_2(cr, I) were estimated by comparison with those of its constituent oxides. $S°(298.15\ K)$ was calculated as the sum of the entropy contributions from H^+ and BO_2^- in HBO_2(c) suggested by Kelley and Kubaschewski and Evans.

Fusion Data

Kracek, Morey and Merwin reported the existence of three crystal forms of HBO_2(c), namely HBO_2(cr, I), $T_{fus} = 509 \pm 1K$; HBO_2(cr, II), $T_{fus} = 474.1 \pm 0.5\ K$; and HBO_2(cr, III), $T_{fus} = 449.2 \pm 0.2\ K$. However, there was no solid phase equilibrium found among these crystals. Sokolova, Skuratov, Shemonaeva and Yuldasheva measured the enthalpies of solution in water of HBO_2(cr, I) and HBO_2(cr, II) and derived the enthalpy of transition as $\Delta_{trs} H°(II \rightarrow I, 298.15\ K) = 1.29\ kcal·mol^{-1}$.

Sublimation Data

The value of $\Delta_{sub} H°(298.15\ K)$ is calculated as the difference between the $\Delta_f H°(298.15\ K)$ values for HBO_2(g) and HBO_2(c).

Enthalpy of Formation

The equilibrium pressures of the reaction 1/2 B_2O_3(l) + 1/2 H_2O(g) = HBO_2(g) have been measured by several investigators. Using the equilibrium data reported, the enthalpies of reaction, $\Delta_r H°(298.15\ K)$, were evaluated by both the 2nd and 3rd law methods. The corresponding enthalpies of formation for HBO_2(g) were derived based on the $\Delta_r H°(298.15\ K)$ values obtained by the 3rd law method. The results are presented as follows:

Source	T/K	$\Delta_r H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}

	1148	—	43.2	−135.3 ± 0.4

*The value not used for the calculation of the weighted average of $\Delta_f H°(298.15\ K)$ for HBO_2(g)

Heat Capacity and Entropy

All molecular and spectroscopic constants were taken from White and Mann *et al.*[2] The principal moments of inertia are: $I_A = 0.1155 \times 10^{-39}$, $I_B = 9.1066 \times 10^{-39}$ and $I_C = 9.2221 \times 10^{-39}\ g·cm^2$.

Enthalpy of Formation

The transient thioborine molecule, HBS, has been identified by Kirk and Timms[1] in the mass spectra of the products fromed by the high temperature (1150–1300°C) reaction of hydrogen sulfide on crystalline boron. The best yields of HBS were found at low pressures (<1 torr) but even under thses conditions the half-life is relatively short (<3 min).[1,2] No experimental measurement of its enthalpy of formation has been reported.

We estimate $\Delta_f H°$ from a consideration of bond-energy schemes. A comparison of the values for the H–B stretching force constants in HBS (K = 4.021 × 10^5 dynes/cm) and HBO (K = 4.080 × 10^5 dynes/cm)[3] suggests that the H–B bonds in these two molecules are quite similar. Assuming $\Delta_{at}H°$(H–BO, 298.15 K) = 99.5 $kcal·mol^{-1}$,[3] we calculate $\Delta_f H°(298.15\ K)$ = 10.7 $kcal·mol^{-1}$with $\Delta_f H°$(H, g, 298.15 K) = 52.103 $kcal·mol^{-1}$ and $\Delta_f H°$(BS, g 298.15 K) = 58.1 ± 4.0 $kcal·mol^{-1}$.[3]

A comparison of force constants also suggests that the H–B bonds in BH_3[4] and the B=S bond in BS[3] are similar to those in HBS. Using $\Delta_{at}H°$(H–B, 298.15 K) = $\Delta_{at}H°(BH_3, g, 298.15\ K)/3$ = 87.9 $kcal·mol^{-1}$ and $\Delta_{at}H°$(B=S, 298.15 K) = $\Delta_{at}H°$(BS, 298.15 K) = 141.0 $kcal·mol^{-1}$, we calculate $\Delta_{at}H°(298.15\ K)$ = 228.9 $kcal·mol^{-1}$ which leads to $\Delta_f H°(298.15\ K)$ = 22.3 $kcal·mol^{-1}$. All bond dissociation energies are derived from JANAF data.[3]

A value for $\Delta_{at}H°(298.15\ K)$ can also be obtained from the results of MO calculations on HBS. Thomson[5] has shown that dissociation energies obtained from MO calculations when combined with estimates of the molecular extra correlation energy (MECE) give reliable atomization energies. The change in the relativistic energy between the isolated atoms and molecule is assumed small. It is reasonable to assume that the contribution to the atomization energy from correlation effects would be similar for the isoelectronic molecules HBS and HBO. We estimate the MECE for HBO as 56.5 $kcal·mol^{-1}$ from the difference in the experimental $\Delta_{at}H°$ [3] and the reported Hartree–Fock dissociation energy.[6] This value of MECE when added to the computed dissociation energy[7] of 191.7 $kcal·mol^{-1}$ gives $\Delta_{at}H°(298.15\ K)$ = 248.2 $kcal·mol^{-1}$ which corresponds to $\Delta_f H°$(HBS, g, 298.15 K) = 3.0 $kcal·mol^{-1}$. We believe these three estimates of $\Delta_f H°$(10.7, 22.3, 3.0 $kcal·mol^{-1}$) to be equally probable; therefore, we adopt the mean value of 12.0 $kcal·mol^{-1}$. An uncertainty of ±10.0 $kcal·mol^{-1}$ is assigned which covers the range of possible values.

Heat Capacity and Entropy

The microwave measurements on HBS by Pearson and McCormick[8] have shown that the molecule is linear in its ground state. They observed the millimeter-wave spectra for eight isotopic species and evaluated structural parameters by the substitution method. We adopt their mean values for the H–B and B=S bond lengths.

Sams and Maki[2] have observed the υ_1 vibrational fundamental (2742 cm^{-1}) in the high-resolution infrared spectra of HBS(g). Frequencies (υ_1) were recorded for four isotopic species. The value of υ_1(2742 cm^{-1}) is corrected for the natural isotopic abundances of boron: the correction for the sulfur isotopes is negligible. Values of υ_2 and υ_3 are calculated from force constants by a valence force method.[9] The B=S stretching force constant (K = 6.9 × 10^5 dynes/cm) is estimated from the value for BS (K = 6.7 × 10^5 dynes/cm) by comparison with the B=O stretching force constants for BO and HBO.[3] The bending force constant (K_D = 3.2 × 10^{12} dynes/cm) is taken equal to the value for HBO.[3] Sams and Maki[2] also performed a detailed force field calculation on HBS which gave υ_2 = 635 cm^{-1} for $H^{11}B^{32}S$. Enthalpy of Formation

Kroto *et al.*[1] and Fehler and Turner[2] have independently measured the 584 Å photoelectron spectra of HBS(g). The reported value of 11.11 ± 0.03 eV[1] and 11.12 eV[2] for the first adiabatic ionization potential are in excellent agreement. We adopt an average (11.115 ± 0.03 eV) of these two IP values, and we assume $\Delta_f H°$ = 256.32 ± 0.7 kcal·mol⁻¹ refers to the ionization process HBS(g) + e⁻ + HBS⁺(g) + 2 e⁻ at 0 K. The latter value yields $\Delta_f H°$(HBS⁺, g, 0 K) = 268.4 ± 11.0 kcal·mol⁻¹ when combined with $\Delta_f H°$(HBS, g, 0 K) = 12.1 ± 10.0 kcal·mol⁻¹.[3] The adopted $\Delta_f H°$ value is placed in brackets to emphasize the uncertainty in the estimated $\Delta_f H°$ value[3] for HBS. $\Delta_f H°(298.15\ K)$ corresponds to 270.0 ± 11.0 kcal·mol⁻¹.

Heat Capacity and Entropy

Extensive ab initio MO calculations[4] recently reported for HBS show that the highest occupied orbital is of Π–symmetry and is localized mainly on the sulfur atom. The shape of the first photoelectron band in the HBS spectra[1,2] suggests that this orbital is bonding. The bonding nature of this Π orbital is also predicted from the Walsh diagram[5] for HAB molecules. As a consequence, we would expect the ion to be less strongly bound than the parent molecule. In the related species HCN[6] which has the same orbital ordering as HBS,[4] ionization[7] occurs with a 2.2% increase in the H–C bond length and a 4.7% increase in the C=N bond length. We assume a similar increase in the bond lengths of HBS[3] upon ionization. If the ion was nonlinear, one would expect to find a vibrational spacing in the photoelectron spectra of HBS which could be associated with the bending frequency of the ion. No frequency as low as 764 cm⁻¹ has been observed;[1,2] thus, it is likely that HBS⁺ is linear in its ground state. This prediction is supported by the Walsh diagram.[5] We assume that the ion is linear.

The progression in the first photoelectron band of the HBS spectra has been reported as 955 ± 40 cm⁻¹ [1] and 990 cm⁻¹.[2] By comparison with changes observed in vibrational frequencies on ionization of HCN and HCP,[3,8] the vibrational mode excited is most certainly the B=S stretching frequency, υ_3. We adopt the average (973 cm⁻¹) of these two values. The values of υ_1 and are calculated from estimated force constants by a valence force method.[9] The two force constants are estimated form those for HCN⁺,[8] NCH and NBS.[3] We estimate the uncertainties in our frequencies are no greater than ±50 cm⁻¹ which corresponds to an error in the value of $S°$(298.15 K) of only ±0.12 kcal·mol⁻¹.

The electronic states and upper levels are taken from the photoelectron spectrometric study of Kroto *et al.*[1] Relative term values for the $A^2\Sigma^+$ and $B^2\Sigma^+$ states are calculated as differences in the reported adiabatic ionization potentials.[1] Fehler and Turner[2] have estimated the ground state splitting to be ~300 cm⁻¹ from the observed peak widths in the first band of the HBS photoelectron spectra. We adopt this result since it compares favorably with the splitting (~278 cm⁻¹) observed for the $^2\Pi$ state of the isoelectronic molecules CS^+.[10] Relative term values for the two $^2\Sigma$ states calculated from the adiabatic ionization potentials of Fehler and Turner[2] agree within about 160 cm⁻¹ with the values adopted here. Fehler and Turner[2] have also reported a photoelectron band at 17.9 eV which was not observed by Kroto *et al.*[1] This band could not be definitely assigned to HBS⁺. If this state does exist, it lies above 50000 cm⁻¹ and has a negligible effect on the thermodynamic functions of the ion. We prefer not to include it. Kroto *et al.*[1] have interpreted their photoelectron results in terms of a linear configuration for the three observed states of HBS⁺. Thus, we feel our functions are not significantly influenced by the use of the ground state vibrational frequencies and rotational constant for the excited states.

Rotational Constant: B_o = [5.807235] cm^{-1}

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ was calculated from appearance potentials reported by Fehlner and Koski[1] and the JANAF Thermochemical Table.[2] For example:

	$\Delta_r H°(0\ K)$
$B_2H_6(g) \rightarrow BH_2^+(ion) + BH_2(g) + H_2(g)$	13.4 eV
$BH_2(g) \rightarrow BH_2^+(ion)$	9.8 eV
$B_2H_6(g) \rightarrow 2\ BH_2(g) + H_2(g)$	3.6 eV

The $\Delta_f H°$ data is summarized below.

Source	Method	$\Delta_f H°(298.15\ K)$, $kcal·mol^{-1}$
[2]	Appearance Potentials	48
[3]	Estimate	66
[4]	Estimate	93

Heat Capacity and Entropy

The bond distance B–H = 1.20 Å was estimated from a consideration of BH(g), BH_3(g) and other molecules. The bond angle H–B–H = 180° and the electronic configuration of the ground state [$^2A_2$] were estimated by Jordan and Longuet Higgins.[4] The frequencies were estimated assuming valence forces, Herzberg,[5] and using force constants, $k_1 = 3.5 \times 10^5$ dynes cm^{-1} and $k\delta 1' = 0.35 \times 10^5$ dynes cm^{-1}, estimated from BH_3, Shepp and Bauer.[6]

Ground State Quantum Weight: [2] $\sigma = 2$

Point Group: [C_{2h}]

Bond Distances: B–O = [1.27] Å; O–H = [0.97] Å

Bond Angles: H–O–B = [105]°; O–B–O = [180]°

Product of the Moments of Inertia: $I_A I_B I_C = [24.2754 \times 10^{-117}]\ g^3·cm^6$

Enthalpy of Formation

The value of $\Delta_f H°(B(OH)_2, g, 298.15\ K)$ was calculated by using the bond energy, $D°_0(B–OH) = 132.7\ kcal·mol^{-1}$, and the enthalpies of formation for B(g) and OH(g) as 132.80 and 9.33 $kcal·mol^{-1}$, respectively.

Heat Capacity and Entropy

The vibrational frequencies were estimated by comparison with those for $BO_2(g)$, $B(OH)_3(g)$ and other related molecules. The bond distances and angles were estimated by comparison with those for $BO_2(g)$ and $H_2O_2(g)$ molecules. The molecular configuration is assumed to be trans which is considered as more stable than the cis–form. The principal moments of inertia are: $I_A = 0.2688 \times 10^{-39}$, $I_B = 9.3699 \times 10^{-39}$, and $I_C = 9.6387 \times 10^{-39}\ g·cm^2$.

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ was calculated from appearance potentials by Fehlner and Koski.[1] For example:

$B_2H_6(g) \rightarrow BH_3^+(ion) + BH_3(g)$	13.1 eV
$BH_3^+(ion) \rightarrow BH_3(g)$	−11.4 eV
$B_2H_6(g) \rightarrow 2\ BH_3(g)$	1.7 eV

The enthalpy of formation data is summarized below.

Reaction: $B_2H_6(g) \rightarrow 2\ BH_3(g)$*

*The auxiliary $\Delta_f H°(B_2H_6, g, 298.15\ K)$ was from the JANAF table dated December 31, 1964.

Heat Capacity and Entropy

The molecular configuration, [planar, H–B–H angle 120°], was estimated by Shepp and Bauer[8] as well as by Jordan and Longuet Higgins.[2] In addition, Shepp and Bauer estimated the bond distance and the vibrational frequencies. Jordan and Longuet Higgins estimated the electronic configuration [$^1A_1$]. The principal moments of inertia are: $I_A = I_B = 0.3378 \times 10^{-39}$ and $I_C = 0.6757 \times 10^{-39}$ $g·cm^2$.

$S°(298.15\ K) = 88.74 \pm 0.4\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 444.1 \pm 0.2\ K$
$T_{dcm} = [330\ K]$

$\Delta_f H°(0\ K) = -1080 \pm 0.8\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1094 \pm 0.8\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° =$ Unknown

Enthalpy of Formation

The enthalpy of formation of $\Delta_f H°(H_3BO_3, cr, 298.15\ K)$ was taken from Good and Mansson *et al.*[1] The value was derived based on the following measurements.

	$\Delta_r H°(298.15\ K)$, kcal·mol^{-1}
$B(cr) + 0.75\ O_2(g) + 18.674\ HF \cdot 57.219\ H_2O(l) = HBF_4 \cdot 14.674\ HF \cdot 58.719\ H_2O(l)$	-173.4 ± 0.2
$H_3BO_3(cr) + 18.674\ HF \cdot 55.719\ H_2O(l) = HBF_4 \cdot 14.674\ HF \cdot 58.719\ H_2O(l)$	$+14.6 \pm 0.1$

The enthalpy of solution of H_3BO_3(cr) in water have been measured by many investigators. Fasolino[2] obtained the value, $\Delta_r H°(298.15\ K) = 5.45 \pm 0.01$ kcal·mol^{-1} for the reaction $H_3BO_3(cr) + 504\ H_2O(l) = H_3BO_3 504\ H_2O(sol)$ which leads to $\Delta_f H°(H_3BO_3 504\ H_2O, sol, 298.15\ K) = -256.02$ kcal·mol^{-1}. The $\Delta_r H°(298.15\ K)$ value is in reasonable agreement with the value reported by Smisko and Mason[3] in which the enthalpies of solution and dilution of H_3BO_3(cr) were given. The enthalpies of solution of H_3BO_3(cr) in water measured y other previous investigators were reviewed by Fasolino.[2]

Heat Capacity and Entropy

The low temperature (16–298.15 K) heat capacities were reported by Johnston and Kerr.[5] The heat capacities above 300 K were estimated with those of its constituent oxides. $S°(298.15\ K)$ was obtained from Johnston and Kerr using $S°(17\ K) = 0.18$ kcal·mol^{-1}.

Fusion Data

The value of T_{fus} was taken from Kracek and Morey *et al.*[6] However, H_3BO_3(cr) is in a metastable state at T_{fus}. Measurements of the decomposition pressure of H_3BO_3(cr) to form HBO_2(cr, II or III) and H_2O(g) have been made by Menzel, Schulz and Deckert,[7] Thiel and Stiebeneck,[8] Stackelberg, Quatran and Dressel,[9] and Bezzi and Hazaki.[10] The decomposition pressures of the system $H_3BO_3(cr) = H_2O(g) + HBO_2$(cr, I), at the temperatures of 312 to 352 K, have been reported by West.[11]

Decomposition Data

The decomposition temperature (T_{dcm}) is calculated as the temperature at which the Gibbs energy change of the reaction $H_3BO_3(cr) \rightarrow HBO_2(cr) + H_2O(g)$ is zero.

Sublimation Data

The enthalpy of sublimation, $\Delta_{sub} H°(298.15\ K)$, is derived as the difference between the $\Delta_f H°(298.15\ K)$ values for H_3BO_3(g) and H_3BO_3(cr).

Enthalpy of Formation

The vapor pressures of H_3BO_3(cr), 109–140°C, were measured by Stackelberg, Quatram and Dressel.[1] Using the vapor pressures reported, the enthalpies of sublimation of H_3BO_3(cr) were evaluated to be 24.4 ± 0.6 and 24.22 kcal·mol^{-1} by the 2nd and 3rd law methods, respectively. $\Delta_f H°(H_3BO_3, g, 298.15\ K)$ was calculated from the $\Delta_f H°(H_3BO_3, cr, 298.15\ K)$ and $\Delta_{sub} H°(H_3BO_3, cr, 298.15\ K)$. The $\Delta_{sub} H°$(298.15 K) value adopted is the average of the 2nd and 3rd law values mentioned previously.

Heat Capacity and Entropy

The molecular structure and constants were taken from Pistorius[2] based on an x-ray diffraction study on H_3BO_3(cr) by Zachariasen.[2] The O-H bond distance was reestimated as 0.96 Å instead of 0.88 Å reported. From the existing infrared and Raman spectra data on H_3BO_3(cr) and its aqueous solution, Pistorius carried out a normal coordinate treatment by means of Wilson's F-G matrix method and calculated the fifteen fundamental frequencies for H_3BO_3(cr). For H_3BO_3(g), twelve reported frequencies were used and corrected to the average isotopic species. The three torsional frequencies, 824(1) and 209(2) cm^{-1}, were not used based on an assumption that there are three internal rotations, i.e. three OH groups, each rotates about its own B-O bond. Employing the model of having three free rotating OH tops, the value of $S°$(400 K) was evaluated statistically as 75.522 kcal mol^{-1}. The corresponding value obtained by using the 2nd law value of $\Delta_{sub} H°$(400 K), 48.39 ± 1.42 kcal·mol^{-1}, for the reaction H_3BO_3(g), is 75.97 ± 1.43 kcal·mol^{-1} which is in good agreement with the $S°$(400 K) value based on a model having three free rotating groups. Thus the assumed model is adopted to evaluate the thermodynamic functions. The reduced moment of inertia for the OH top is I_r = 1.15321 × 10^{-40} g cm^2 . The principal moments of inertia are: $I_A = I_B$ = 8.3334 × 10^{-39} and I_C = 16.6669 × 10^{-39} g·cm^2. The infrared absorption spectrum of H_3BO_3(g) was observed under conditions where one atmosphere of water vapor with a path length of approximately one meter as background, by Greene, Leroi, Randall *et al.*[4] The following fundamentals were obtained: 3220 cm^{-1} S, 1490 cm^{-1} S, 1199 cm^{-1} S, 881 cm^{-1} W, and 669 cm^{-1} W.

PREVIOUS: December 1964 (1 atm) CURRENT: December 1964 (1 bar)

$S°(298.15\ K) = 106.61\ J·K^{-1}·mol^{-1}$

$\Delta_f H°(0\ K) = -218.19 \pm 2.30\ kJ·mol^{-1}$

$\Delta_f H°(298.15\ K) = -226.90 \pm 2.30\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of reaction of KBH_4(cr) with hydrochloric acid has been measured by solution calorimetry and reported by Johnson, Schumm, Wilson, and Prosen.[4]

$$KBH_4(cr) + HCl(g) + 3H_2O(l) \rightarrow KCl(cr) + H_3BO_3(cr) + 4H_2(g)\ \Delta_r H° = -84.62 \pm 0.44\ kcal·mol^{-1}$$

The $\Delta_f H$(298.15 K) values for HCl(g) and H_3BO_3(cr) were obtained from the JANAF Tables. The $\Delta_f H°$(298.15 K) value for KCl(cr) was calculated from $\Delta_f H°(K^+, aq, \infty, 298.15\ K) = -60.32\ kcal·mol^{-1}$, $\Delta_f H°(Cl^-, aq, \infty, 298.15\ K) = -39.952\ kcal·mol^{-1}$ and $\Delta_{dil} H° = 4.12\ kcal·mol^{-1}$ obtained by Evans.[4] $\Delta_f H°$(298.15 K) for H_2O(l) was obtained from Evans.[4] Unpublished data of The Dow Chemical Company Thermal laboratory give a value of $\Delta_f H°(298.15\ K) = -55.0 \pm 1.0\ kcal·mol^{-1}$ by solution calorimetry.

Heat Capacity and Entropy

C_p and $S°$ at temperatures below 298.15 K were reported by Furukawa, Reilly, and Henning.[2] The values of C_p in the range from 298.15 to 700 K were obtained from Douglas and Harman.[3] These two sets of C_p data were plotted and joined smoothly at 298.15 K. The values of C_p above 700 K are estimated by graphical extrapolation.

Decomposition Data

The temperature of decomposition (into constituent elements) was estimated to be 770 K, according to a report by Douglas and Harman.[3]

T_{fus} = [750] K

$\Delta_f H°(0\ K) = -180.391 \pm 0.21\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -190.464 \pm 0.21\ kJ·mol^{-1}$
$\Delta_{fus}H°$ = Unknown

Enthalpy of Formation

The enthalpy of formation of LiBH4(cr) was calculated from the solution calorimetry of Davis, Mason and Stegeman.[1] The enthalpies of reaction were measured for the following reactions:

$LiBH_4(cr) + 1.25(HCl·200\ H_2O) + 3\ H_2O(l) \rightarrow (NaCl + H_3BO_3 + 0.25\ HCl)247\ H_2O + 4\ H_2(g)$ $\Delta H_1(298.15\ K) = -72.14\ kcal\ mol^{-1}$

$LiCl·60\ H_2O + H_3BO_3·60\ H_2O + 0.25(HCl·506\ H_2O) \rightarrow (LiCl + H_3BO_3 + 0.25\ HCl)·247\ H_2O$ $\Delta H_2(298.15\ K) = 0.00\ kcal\ mol^{-1}$ (assumed)

$H_3BO_3·60\ H_2O + \infty\ H_2O \rightarrow H_3BO_3·\infty\ H_2O$ $*\Delta H_3(298.15\ K) = 0.200\ kcal\ mol^{-1}$

The summation of the above reactions yields:

$LiBH_4(cr) + 1.25(HCl·200\ H_2O) + 3\ H_2O(l) + \infty\ H_2O \rightarrow LiCl·60\ H_2O + H_3BO_3·\infty\ H_2O + 0.25(HCl·508\ H_2O) + 4\ H_2(g)$ $\Delta H(298.15\ K) = -71.94$

*This $\Delta_f H°(298.15\ K)$ value was obtained from J. Smisko and L. S. Mason loc. cit.

The enthalpy of formation of lithium borohydride crystal was calculated to be −45.522 kcal mol^{-1} with the following auxiliary data:

Compound	$\Delta_f H°(298.15\ K)$	Source
HCl (508 H_2O)	−39.815	HCl(g) JANAF; dilution data from NBS Rept. 8504, 1 July 1964 Appendix III by W. H. Evans

LiCl (60 H_2O)	−106.023	Li^+ see NaBH4 table; Cl^- and dilution data, W. H. Evans, loc. cit.
H_3BO_3(∞H_2O)	−256.05	JANAF H_3BO_3(cr) and dilution data from J. Smisko and L. S. Mason, J. Am. Chem. Soc. **72**, 3679 (1950).

Heat Capacity and Entropy

The low temperature heat capacities, 15.72–302.88 K, were obtained from the measurements by Hallett and Johnston.[2] The C_p values above 298.15 K were estimated by comparison with the C_p's for $NaBH_4$.

The entropy was based on $S°(15\ K, extrap) = 0.0874\ cal·K^{-1}·mol^{-1}$ reported by Hallett and Johnston.[2]

Fusion Data

T_{fus} was estimated by comparison with the T_{fus} for $NaBH_4$.

PREVIOUS: March 1963 CURRENT: December 1964

$S°(298.15\ K) = 101.39\ J·K^{-1}·mol^{-1}$
$T_{trs} = 189.9\ K$
$T_{fus} = 770\ K$

$\Delta_f H°(0\ K) = -183.3 \pm 0.39\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -191.84 \pm 0.39\ kJ·mol^{-1}$
$\Delta_{trs} H° = 0.999\ kJ·mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

The enthalpy of formation is calculated from the solution calorimetry of Davis, Mason and Stegeman.[1] The enthalpies of reaction and mixing were measured for the following reactions:

$NaBH_4 + 1.25(HCl·200H_2O) \rightarrow (NaCl + H_3BO_3 + 0.25HCl)·247H_2O + 4H_2$ $\Delta_r H = -63.880\ kcal·mol^{-1}$
$NaCl·60H_2O + H_3BO_3·60H_2O \rightarrow (NaCl + H_3BO_3)·120H_2O$ $\Delta_r H = -0.026\ kcal·mol^{-1}$
$NaCl + (H_3BO_3)·120H_2O + 0.25(HCl·508H_2O) \rightarrow (NaCl + H_3BO_3 + 0.25HCl)·247H_2O$ $\Delta_r H = +0.083\ kcal·mol^{-1}$
$H_3BO_3·60H_2O + \infty H_2O \rightarrow H_3BO_3\infty H_2O$ $\Delta_r H = +0.068\ kcal·mol^{-1}$

The summation of the above equations yields:

$NaBH_4(cr) + 1.25(HCl·200H_2O) + 3H_2O(l) + \infty H_2O \rightarrow NaCl·60H_2O + H_3BO_3\infty H_2O + 0.25(HCl·508H_2O) + 4H_2(g)$
$\Delta_r H = -63.869\ kcal·mol^{-1}$

The $\Delta_f H(298.15\ K)$ values for HCl were obtained from JANAF value[5] for HCl(g) and enthalpy of dilution data of Evans.[6] The $\Delta_f H(298.15\ K)$ for $H_2O(l)$ value was obtained from Evans.[6] The $\Delta_f H(298.15\ K)$ value for NaCl was obtained from JANAF value[5] of NaCl(cr) together with dilution data from Evans.[6] The $\Delta_f H(298.15\ K)$ value for H_3BO_3 was obtained from JANAF value[5] for H_3BO_3(cr) together with dilution data of Smisko and Mason.[2]

Heat Capacity And Entropy

The low temperature heat capacity (15.76–301.26 K) was obtained from Johnston and Hallett.[3] In the area of transition (169–193.5 K) the average $\Delta_{trs} H = 635.3\ cal·mol^{-1}$ and the average $\Delta_{trs} S = 3.35\ cal·K^{-1}·mol^{-1}$ were adopted from Johnston and Hallett.[3] Using the present base line these ΔH and ΔS values yield a enthalpy of transition of $0.2388\ kcal·mol^{-1}$. The low temperature heat capacity was fitted with the smoothed enthalpy capacity data (298.15–700 K) of Douglas and Harman.[4] The heat capacity above 700 K was extrapolated from the plot of both sets of data.

Transition Data

The temperature and heat of transition were obtained from Johnston and Hallett.[3]

Fusion Data

The fusion data was obtained from Douglas and Harman.[4]

Enthalpy of Formation

The ratio, $D_0°(BF)$ / $(\Delta_{at}H°(BF_3, g, 0\ K)/3) = 1.177$, was applied to BI_3 giving $D_0°(BI) = 84.4\ kcal·mol^{-1}$ and $\Delta_f H°(298.15\ K) = 73 \pm 10\ kcal·mol^{-1}$.

Heat Capacity and Entropy

The bond length was first estimated by comparison with the ratio of the bond lengths in the other boron trihalides and monohalides. The vibrational frequency was then calculated using Guggenheimer's Relation[1] which was checked using BBr_3 and shown to give an excellent fit. The quantity $x_e\mu^{1/2}$, where μ is the reduced mass, has been shown to be for similar molecules and its value was transferred from BBr to give x_e and $\omega_e x_e$ for BI. α_e was then calculated using the Morse potential function and B_e was determined from the bond length. The ground state configuration was assumed to be the same as that in BBr.

Ground State Quantum Weight: [2] $\sigma = 2$

Point Group: [C_{2v}]

Bond Distance: B–I = [2.06] Å

Bond Angle: I–B–I = [120]°

Product of the Moments of Inertia: $I_A I_B I_C = [3.331449 \times 10^{-113}]\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation was estimated by analogy with BF_3, specifically the ratio $\Delta_f H°(BX_3 \rightarrow BX_2 + X) / \Delta_f H°(BX_3 \rightarrow B + 3X)$ was taken as 0.347.

Heat Capacity and Entropy

The vibrational frequencies were obtained from force constants transferred from the trihalide given by Herzberg.[1] The bond length was taken between those of the mono and trihalide and the angle was estimated to be the same as that in the trihalides. The ground state quantum weight was taken as two on account of the one unpaired electron.

The principal moments of inertia are: $I_A = 1.8266 \times 10^{-39}$, $I_B = 134.1401 \times 10^{-39}$, and $I_C = 135.9667 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: [1] $\sigma = 6$
Point Group: D_{3h}
Bond Distance: B–I = [2.03 ± 0.03] Å
Bond Angle: I–B–I = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [4.420581 \times 10^{-111}]\ g^3·cm^6$

Enthalpy of Formation

Koski *et al.*[2] measured the appearance potential of the B^+ ion from BI_3. Assuming the reaction $BI_3 + e^- \rightarrow B^+ + 3I + 2e^-$, one can calculate the enthalpy of atomization of BI_3 as 8.31 ± 0.5 eV. The analogous reaction for BBr_3 can be checked independently and shows the process to be valid. This value leads to $\Delta_f H°(298.15\ K) = 17.0 \pm 12\ kcal·mol^{-1}$ if the process is assumed to occur at 298.15 K.

Heat Capacity and Entropy

Vibrational frequencies were taken from Wentink and Tiensuu,[1] modified according to the natural abundance of boron. The B–I distance was estimated by Koski *et al.*[2] and the angle was estimated by analogy with the other boron trihalides. The three principal moments of inertia are: $I_A = I_B = 130.2616 \times 10^{-39}$, and $I_C = 260.5232 \times 10^{-39}\ g·cm^2$.

PREVIOUS: December 1964 (1 atm) CURRENT: December 1964 (1 bar)

$S°(298.15\ K) = 79.98 \pm 0.12\ J \cdot K^{-1} \cdot mol^{-1}$

$T_{fus} = 1220 \pm 3\ K$

$\Delta_f H°(0\ K) = -990.1 \pm 8\ kJ \cdot mol^{-1}$

$\Delta_f H°(298.15\ K) = -995.0 \pm 8\ kJ \cdot mol^{-1}$

$\Delta_{fus} H° = 31.38 \pm 4.2\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Shartsis and Capps[1] measured the enthalpies of solution in 2N nitric acid of various K_2O–B_2O glass and crystalline mixtures containing 1.1–41.0 mole % of K_2O. When these results are extrapolated to 50 mole %, we obtain $\Delta_{sol}H°$ (25°C) = −11.9 ± 2 kcal·mol^{-1} for KBO_2(cr) + HNO_3(27.75 H_2O, aq) + H_2O(l) → KNO_3(27.75 H_2O, aq) + H_3BO_3(27.75 H_2O, aq) which leads to $\Delta_f H°(KBO_2$, cr, 298.15 K) = −237.8 ± 2 kcal·mol^{-1}, using the following auxiliary data: $\Delta_f H°(HNO_3 \cdot 27.75\ H_2O$, aq) = −256.37 kcal·mol^{-1}.[4] The value, $\Delta_f H°(KBO_2$, cr, 298.15 K) = −237.8 ± 2 kcal·mol^{-1}, is adopted in the tabulation. Since the enthalpies of formation of $LiBO_2$(cr) and $NaBO_2$(cr) derived from the enthalpy of solution data are in good agreement with those values[5] adopted, their enthalpy of solution data should be reasonably reliable, although the calorimetric treatment was loose.

Heat Capacity and Entropy

Paukov *et al.*[6] have measured low temperature heat capacities from 12.11 to 312.22 K in an adiabatic calorimeter. The adopted C_p are derived from their experimental heat capacites by a polynomial curve fitting technique. The derived entropy $S°(298.15\ K)$ is 19.116 ± 0.03 cal·K^{-1}·mol^{-1} based on $S°(12.11\ K) = 0.0353$ cal·K^{-1}·mol^{-1}. Heat capacities above 310 K are estimated by comparison with those of $NaBO_2$(cr)[5] since both $NaBO_2$ and KBO_2 have same type of crystal structure.[7]

Thermal analysis data[8] have been interpreted in terms of a crystal transition at 785°C. Details of these studies are not available and it is not clear how reliable this interpretation is. We note, however, that the reported temperature (785°C) is essentially the same as the eutectic temperature of KBO_2 with $K_2B_4O_7$.[9, 10] We tentatively adopt a single C_p curve without a transition.

Fusion Data

Our analysis of several sets of binary phase data[8, 9, 11–14] yields the enthalpy of fusion, $\Delta_{fus}H° = 7.5 \pm 1$ kcal·mol^{-1}. The adopted melting point (947°C) is a weighted average of the observed data[8–15] which vary from 940 to 950°C.

PREVIOUS: CURRENT: June 1971

$S°(298.15\ K)$ = [88.455] $J·K^{-1}·mol^{-1}$
T_{fus} = 1220 ± 3 K

$\Delta_f H°(298.15\ K)$ = [−980.730] $kJ·mol^{-1}$
$\Delta_{fus}H°$ = 31.38 ± 4.2 $kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(KBO_2, l, 298.15\ K)$ is calculated from that of the crystal by adding $\Delta_{fus}H°$ and the difference in enthalpy, $H°(1220\ K)–H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The constant heat capacity of the liquid is estimated to be 36 $J·K^{-1}·mol^{-1}$ based on that of $LiBO_2$(l)[1] which was derived from high temperature enthalpy measurements. A glass transition is assumed at 812 K below which the heat capacities are assumed to be the same as the crystal.

$S°(KBO_2, l, 298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

Refer to the crystal table for details.

Vaporization Data

The boiling point is calculated as the temperature at which the fugacity is 1 atm for $KOB_2(l) \rightarrow KBO_2(g)$. The enthalpy of vaporization is the difference in $\Delta_f H°$ at the boiling point between liquid and gas.

Ground State Quantum Weight: 1 $\sigma = 1$

Point Group: C_s

Bond Distances: K–O = [2.4] Å; O–B = [1.36] Å; B–O = [1.20] Å

Bond Angles: K–O–B = [90]°; O–B–O = [180]°

Product of the Moments of Inertia: $I_A I_B I_C = [5.790543 \times 10^{-114}]\ g^3 \cdot cm^6$

Enthalpy of Formation

Jensen[1] determined the equilbrium constants for the reaction: $K(g) + HBO_2(g) \rightarrow KBO_2(g) + H(g)$ by flame studies. This technique involved several assumptions, the most basic of which is that boron added to $H_2/N_2/O_2$ flames was converted completely to HBO_2. The hydrogen atom concentration was taken from previous studies on such flames. Potassium metaborate was assumed to be formed in the flame. The concentration of K atom was determined by atomic absorption spectrophotometry. JANAF 3rd law analysis of his equilibrium constant equation in the temperature range from 2000 to 2600 K yields $\Delta_f H°(298.15\ K) = 3.66 \pm 0.54\ kcal \cdot mol^{-1}$and the drift is $1.26\ cal \cdot K^{-1} \cdot mol^{-1}$. (2nd law enthalpy of reaction is $\Delta_r H°(298.15\ K) = 0.78\ kcal \cdot mol^{-1}$.) Using the 3rd law $\Delta_r H°(298.15\ K)$ and JANAF auxiliary data, we obtain $\Delta_f H°(KBO_2, g, 298.15\ K) = -161.1\ kcal \cdot mol^{-1}$. The uncertainty in this measurement was about $\pm 6\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

Seshadri, Nimon and White[2] observed the infrared spectra of KBO_2 in an argon matrix and made a complete assignment of all six fundamentals which are adopted in the tabulation. The uncertainty of the calculated statistical entropy at 298.15 K is estimated to be ± 1 eu which is due to the magnitude of the matrix shifts from the free molecule spectrum, particularly for the lower frequency modes.

The molecular structure, bond distance and bond angle of KBO_2(g) are assumed to be the same as those of $LiBO_2$(g) and $NaBO_2$(g),[1] except the bond distance K–O which was estimated to be intermediate between those of potassium fluoride and chloride. The principal moments of inertia are: $I_A = 6.1073 \times 10^{-39}$, $I_B = 27.8891 \times 10^{-39}$, and $I_C = 33.9965 \times 10^{-39}\ g \cdot cm.^2$

$S°(298.15\ K) = 51.73 \pm 0.2\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 1117 \pm 1\ K$

$\Delta_f H°(0\ K) = -1013.7 \pm 0.8\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1019.2 \pm 0.8\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 33.81 \pm 0.5\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Sinke[1] measured calorimetrically the enthalpy of solution of $LiBO_2$(cr) in 0.5 N HNO_3, $\Delta_{sol}H°(25°C) = -10.93 \pm 0.05$ kcal·mol^{-1} for $LiBO_2$(cr) + HNO_3(aq, 111 H_2O) → H_3BO_3(aq, 111 H_2O) + $LiNO_3$(aq, 111 H_2O), which leads to the adopted enthalpy of formation, $\Delta_f H°(LiBO_2$, cr, 298.15 K) = -243.6 ± 0.2 kcal·mol^{-1} using the following auxiliary data: $\Delta_f H°(HNO_3 \cdot 111\ H_2O$, aq, 298.15 K) = −49.411 kcal·mol^{-1},[2] $\Delta_f H°(H_2O$, l, 298.15 K) = −68.315 kcal·mol^{-1},[2] $\Delta_f H°(H_3BO_3 \cdot 111\ H_2O$, aq, 298.15 K) = −256.336 kcal·mol^{-1} [2] and $\Delta_f H°(LiNO_3 \cdot 111\ H_2O$, aq, 298.15 K) = −115.944 kcal·mol^{-1}.[3]

Shartsis and Capps[4] measured enthalpies of solution in 2N nitric acid of various Li_2O–B_2O_3 glass and crystalline mixtures containing 2.5–48.4 mole % of Li_2O. When their results are extrapolated to 50 mole %, we obtain $\Delta_{sol}H°(25°C) = -10.8 \pm 0.5$ kcal·mol^{-1} for $LiBO_2$(cr) + HNO_3(27.75 H_2O, aq) + H_2O(l) → $LiNO_3$(27.75 H_2O, aq) + H_3BO_3(27.75 H_2O, aq). The calculated enthalpy of formation is based on the following data: $\Delta_f H°(HNO_3 \cdot 27.75\ H_2O$, aq, 298.15 K) = −49.433 kcal·mol^{-1},[2] $\Delta_f H°(LiNO_3 \cdot 27.75\ H_2O$, aq, 298.15 K) = −115.854 kcal·mol^{-1} [5] and $\Delta_f H°(H_3BO_3 \cdot 27.75\ H_2O$, aq, 298.15 K) = −256.37 kcal·mol^{-1}.[6] The value is $\Delta_f H°(LiBO_2$, cr, 298.15 K) = -243.9 ± 0.5 kcal·mol^{-1}, which is in very good agreement with the adopted value.

Heat Capacity and Entropy

Stull *et al.*[7] measured low temperature C_p data from 15 to 320 K. We use their smoothed C_p values to derive $S°(298.15\ K) = 12.36 \pm 0.05$ cal·K^{-1}·mol^{-1} based on $S°(15\ K) = 0.017$ cal·K^{-1}·mol^{-1}. McDonald[8] determined high temperature enthalpy data from 288 to 1116 K by drop calorimetry. The low temperature C_p and high temperature enthalpy data are smoothly joined at 298.15 K by a polynomial curve fitting technique. The average deviation of the observed enthalpy data from the adopted values is about 0.3% in the temperature range from 428–1062 K, and the maximum is 0.56% at 922 K. The C_p values above T_{fus} are extrapolated from the adopted polynomial function.

Turdakin and Tarasov[9] also measured low temperature heat capacities (55–300 K) in an adiabatic calorimeter. Their values deviate from the adopted C_p by approximately 2%.

Melting curves from binary phase studies[10–12] have been interpreted in terms of a crystal transition near 800°C, although the most recent paper[13] indicated no transition. Two high-pressure polymorphs have been observed[14] but there is no evidence of their stability at atmospheric pressure. Enthalpy data[8] showed no obvious transition near 800°C; points at 829 and 815°C showed reasonable premelting contributions of about 200 and 300 kcal·mol^{-1}, respectively. Although this evidence does not preclude the existence of a transition, definite evidence would be needed to establish such a transition.

Fusion Data

Refer to the liquid table for details.

[3]This value, ($LiNO_3 \cdot 111\ H_2O$, aq $\Delta_f H°298.15\ K) = -115.944$ kcal·mol^{-1}, is calculated based on the follwoing auxiliary data:
a. $\phi_L = 0.171$ kcal mol^{-1} for $LiNO_3(\infty\ H_2O) \rightarrow LiNO_3 \cdot (111\ H_2O)$ ϕ_L was obtained fromV.B. Parker, U. S. Nat. Bur. Stand., NSRDS–NBS 2, 66 pp. (1965).
b. $\Delta_f H°(LiNO_3$ [aq, ∞], 298.15 K) = −116.115 kcal·mol^{-1}.
This value is the sum of $\Delta_f H°(Li^+$ [aq, ∞] 298.15 K) = −66.555 kcal·mol^{-1} and $\Delta_f H°(NO_3^-$ [aq, ∞], 298.15 K) = 49.56 kcal·mol^{-1}.[2]
The former is derived from $\Delta_f H°(LiOH$ [aq, ∞], 298.15 K = −121.525 kcal·mol^{-1} and $\Delta_f H°(OH^-$ [aq, ∞] = −54.97 kcal·mol^{-1}.[2]
[4]L. Shartsis and W. Capps. J. Am. Chem. Soc. **37**, 27 (1954).
[5]This value, −115.854 kcal·mol^{-1}, is calculated from $\Delta_f H°(LiNO_3$ [aq. ∞], 298.15 K = −116.115 kcal·mol^{-1} and $\phi_L = 0.261$ kcal·mol^{-1} for $LiNO_3(\infty\ H_2O) \rightarrow LiNO_3 \cdot (27.75\ H_2O)$ reported by V. B. Parker, U. S. Nat. Bur. Stand. NSRDS–NBS 2, 66 pp. (1965).
[6]This value, −256.37 kcal·mol^{-1}, is extrapolated from the enthalpies of formation of $H_3BO_3 \cdot 60H_2O$ and $H_3BO_3 \cdot 100\ H_2O$ listed by NBS.[2]

PREVIOUS: December 1964 CURRENT: June 1971

$S°(298.15\ K) = [65.547]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1117 \pm 1\ K$

$\Delta_f H°(298.15\ K) = [-1000.259]\ kJ·mol^{-1}$
$\Delta_{fus}H° = 33.81 \pm 0.5\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(LiBO_2, l, 298.15\ K)$ is calculated from that of the crystal by adding $\Delta_{fus}H°$ and the difference in enthalpy, $H°(1117\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

McDonald[1] *measured high temperature enthalpy data of the liquid from 1118 to 1707 K by drop calorimetry. The adopted heat capacities* are derived from his observed data. The average deviation of the observed enthalpy data from the adopted values is about 0.1%. A glass transition is assumed at 745 K below which the C_p is assumed to be the same as that of the crystal.

$S°(LiBO_2, l, 298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

The adopted enthalpy of fusion, $\Delta_{fus}H°(1117\ K) = 8.08 \pm 0.12\ kcal·mol^{-1}$, is calculated from the observed enthalpies[1] by use of the adopted C_p functions of both crystal and liquid.

Petit and Jaeger[2] derived $\Delta_{fus}H°(1109\ K) = 7.4\ kcal·mol^{-1}$ from phase data for the $LiBO_2$–LiF system. Darmois and Zarzycki[3] determined $\Delta_{fus}H°(1113\ K) = 8.3 \pm 0.6\ kcal·mol^{-1}$ from cryoscopic studies involving several secondary components.

Vaporization Data

The boiling point is calculated as the temperature at which the fugacity is 1 atm for $LiBO_2(l) \rightarrow LiBO_2(g)$. The enthalpy of vaporization is the difference in $\Delta_f H°$ at the boiling point between liquid and gas.

Prophet[4] determined the boiling point under argon atmosphere as 2050 ± 100 K which is in good agreement with the value calculated.

Enthalpy of Formation

Jensen[1] determined the equilibrium constants for reaction (A) Li(g) + HBO_2(g) $LiBO_2$(g) + H(g) by flame studies. This technique involves several assumptions, the most basic of which is that boron added to $H_2/N_2/O_2$ flames is converted completely to HBO_2. The hydrogen atom concentration was taken from previous studies on such flames. Lithium metaborate was assumed to be formed in the flame. The concentration of Li atoms was determined by atomic absorption spectrophotometry. JANAF 3rd law analysis of his equilibrium constant equation in the temperature range from 2000 to 2600 K yields $\Delta_f H°(298.15\ K) = -2.95 \pm 1.07\ kcal\cdot mol^{-1}$ and the drift 2.47 $cal\cdot K^{-1}\cdot mol^{-1}$ (the 2nd law enthalpy of reaction being $-8.62\ kcal\cdot mol^{-1}$). Using the 3rd law $\Delta_f H°(298.15\ K)$ and JANAF auxiliary data, we obtain $\Delta_f H°(LiBO_2, g, 298.15\ K) = -150.6\ kcal\cdot mol^{-1}$. The uncertainty in this measurement is about 6 $kcal\cdot mol^{-1}$.

Buchler and Berkowitz-Mattuck[2] studied mass spectrometrically the vaporization of lithium metaborate and reported $\Delta_{vap}H°(1160\ K) = 70 \pm 3\ kcal\cdot mol^{-1}$ for $LiBO_2$(l) → $LiBO_2$(g) and $\Delta_{sub}H°(1060\ K) = 79 \pm 3\ kcal\cdot mol^{-1}$ for $LiBO_2$(cr) → $LiBO_2$(g) by a 2nd law method. JANAF reduction to 298.15 K gives vap H(298.15 K) = 78.1 → 3 $kcal\cdot mol^{-1}$ and $\Delta_{sub}H°(298.15\ K) = 82.4 \pm 3\ kcal\cdot mol^{-1}$. They also determined the vapor pressure of $LiBO_2$ at 1160 K as 2.0×10^{-6} atm by comparison with the vapor pressure of silver. JANAF 3rd law analysis of this single vapor pressure point gives $\Delta_{vap}H°(298.15\ K) = 85.0\ kcal\cdot mol^{-1}$ which leads to $\Delta_f H°(LiBO_2, g, 298.15\ K) = -154.0 \pm 3\ kcal\cdot mol^{-1}$. The latter is in good agreement with the value adopted in the tabulation. The 2nd law enthalpies of vaporization and sublimation are probably in error by about 6 $kcal\cdot mol^{-1}$.

Hildenbrand *et al.*[3] measured the total vapor pressure over liquid $LiBO_2$ in the temperature range from 1120 to 1280 K by a torsion-effusion method. Assuming 100% monomeric vapor species, JANAF 3rd law analysis of their vapor pressure data yields the enthalpy of vaporization, $\Delta_{vap}H°(298.15\ K) = 84.47\ kcal\cdot mol^{-1}$, and a drift of $0.93 \pm 1.0\ cal\cdot K^{-1}\cdot mol^{-1}$, this corresponds to $\Delta_{sub}H°(298.15\ K) = 89.0\ kcal\cdot mol^{-1}$. (2nd law heat of vaporization is $\Delta_{vap}H°(298.15\ K) = 83.25 \pm 1.20\ kcal\cdot mol^{-1}$. Using the 3rd law $\Delta_{vap}H°(298.15\ K)$, we obtain $\Delta_f H°(LiBO_2, g, 298.15\ K) = -154.6\ kcal\cdot mol^{-1}$. If there are 10% of $LiBO_2$ dimer molecules present in the vapor phase as suggested by Buchler,[2] the correction in the 3rd law $\Delta_{vap}H°(298.15\ K)$ is about 0.3 $kcal\cdot mol^{-1}$ is about 0.3 $kcal\cdot mol^{-1}$which is much less than the uncertainty assigned to derive $\Delta_{vap}H°(298.15\ K)$. The value, $\Delta_f H°(LiBO, g, 298.15\ K) = -154.6 \pm 3\ kcal\cdot mol^{-1}$, is adopted in the tabulation.

Heat Capacity and Entropy

The adopted vibrational frequencies are obtained from Seshadri, Nimon and White[4] who observed the infrared spectra of $LiBO_2$ in an argon matrix and made a complete assignement of all six fundamentals. The uncertainty of the calculated statistical entropy at 298.15 K is estimated to be 1 $cal\cdot K^{-1}\cdot mol^{-1}$ which is due to the magnitude of the matrix shifts from the free molecule spectrum, particularly for the lower frequency modes.

Buchler and Marram[5] observed only two vibrational frequencies, 1935 and 600 cm^{-1}, in their infrared spectra. These two frequencies are in reasonable agreement with those reported by Seshadri.[4]

By electron diffraction studies, Akishin and Spiridonov[6] determined the molecular structure of gaseous lithium metaborate and found the bond lengths and angles which are adopted in the tabulation. We tentatively select the bond angles Li-O-B as 90 from their reported data, i.e, 90-105 because Seshadri *et al.*[4] treated this bond angle as a parameter in the force constant calculations and found that the best fit to the infrared spectrometric data occurs at approximately 90. A recent electron diffraction study[7] on lithium metaborate confirms the results given by Akishin.[6]

The principal moments of inertia are $I_A = 2.5800 \times 10^{-39}$, $I_B = 11.0962 \times 10^{-39}$ and $I_C = 13.6763 \times 10^{-39}\ g\cdot cm^2$.

PREVIOUS: June 1971 (1 atm) *CURRENT: June 1971 (1 bar)*

$\Delta_f H°(0\ K) = -247.99 \pm 1.55$ kJ·mol^{-1}
$\Delta_f H°(298.15\ K) = -250.91 \pm 1.55$ kJ·mol^{-1}

$S°(298.15\ K) = 14.795$ J·K^{-1}·mol^{-1}
$T_{dcm} = 2600 \pm 100$ K

Enthalpy of Formation

The adopted enthalpy of formation was determined by Wise *et al.*[5] using combustion in fluorine. Other recent calorimetric values are in good agreement as summarized below. Torsion effusion studies of the decomposition BN(cr) → B(am) + 0.5 N_2(g) by Hildebrand and Hall[7] yield essentially the same $\Delta_f H°$ and indicate that the condensation coefficient $\alpha < 6 \times 10^{-3}$ for N_2(g) on the surface of the sample. Use of $\alpha = 6 \times 10^{-3}$ brings the following decomposition studies into reasonable agreement: Langmuir studies by Dreger *et al.*;[8] mass spectrometric studies by Schissel and Williams;[9] and Knudsen effusion studies by Hoch and White.[10]

Source	Reaction	$\Delta_f H°$(298.15 K) kcal·mol^{-1}	$\Delta_f H°$(298.15 K) kcal·mol^{1}

	B(cr) + NF_3(g) → BF_3(g) + 0.5 N_2	−237.77 ± 0.5	−60.1 ± 2
[5]	Combustion in O_2–H_2O	—	−59.9 ± 1.5
[6]	BN(cr) + 1.5 F_2(g) → BF_3(g) + 0.5 N_2	−211.68 ± 0.3	−59.97 ± 0.37

Heat Capacity and Entropy

The low temperature heat capacity was taken from Westrum.[11] The intermediate heat capacity (300–1650°C) was obtained from McDonald and Stull.[12] The high temperature C_p was taken from Prophet and Stull.[13] The heat capacities in the three temperature ranges were plotted and then graphically smoothed. Dworkin *et al.*[1] also reported that heat capacity (50–300 K) not employed in this table.

The entropy was obtained by integration of the heat capacity data from Westrum[11] based upon $S°(10\ K) = 0.0028$ cal·K^{-1}mol^{-1}.

Decomposition Data

Observations by the Dow Chemical Company under contract No. AF 33(616) 6194 show decomposition to elements at 1 atm total pressure at 2600 ± 100 K. The decomposition temperature calculated from these tables is 2832 K; presumably this discrepancy is associated with uncertainties in the high temperature enthalpies of BN(cr), B(cr), and B(l) and the enthalpy of melting of B(cr).

Enthalpy of Formation

The enthalpy of formation is based on $D_0^\circ = 5.7$ eV which was calculated from ω_e and $\omega_e x_e$ observed by Douglas and Herzberg.[1] An uncertainty of ±1.3 eV was assigned from consideration of other information which places the dissociation energy between 4 and 7 eV. The value $D_0^\circ = 4.0 \pm 0.5$ eV was selected by Gaydon[2] from his own extrapolation of the spectroscopic data. An upper limit of $D_0^\circ < 7.0$ eV results from the upper limit for the pressure of BN(cr) → BN(g) obtained from the B^+ ion intensity at 1600°C observed by Akishin and Klodeev.[3] It is likely that the BN(g) pressure is even smaller since it is known that BN(cr) → B(s) + 0.5 N_2(g) and Akishin's pressure limit is the same magnitude as that of B(cr) → B(g). Fesenko[4] reports a standard enthalpy of sublimation of 160 kcal·mol^{-1} for BN(cr) → BN(g) and also gives pressures for BN(g) at 2500 and 3000 K which are stated to be two orders less than the equilibrium pressure of nitrogen. Fesenko's original article is not yet available to us and it is not clear from the abstract whether the values are based on new data or are merely calculations. The *reported pressures yield* $D_0^\circ = 6.2$ eV *but here again the* BN(g) *pressures are of the same magnitude as the* JANAF *values for* B(s) → B(g).

Some estimated values for D_0° (ranging from 5.4 to 6.4 eV) are summarized below along with the experimental evidence.

Source	D_0°(ev)	$\Delta_{sub}H°$(298.15 K), kcal·mol^{-1}	$\Delta_f H°$(298.15 K), kcal·mol^{-1}
Gaydon's extrapolation of spectroscopic data	4.0 ± 0.5	213	153
Linear Birge Sponer extrapolation	5.7	174	114
Fesenko's BN(g) pressures	6.2	161	101
Akishin's upper limit for BN(g) pressure	7.0	145	85
Estimate from geometric mean of $D°$ for B_2 and N_2	5.4	180	120
Estimate from $D°$ for series N_2, CN, BN, BeN	5.6	177	117
Estimate $M_2 + N_2 = 2$ MN for M=B from M=C	6.0	166	106
Estimate from arithmetic mean of $D°$ *for* B_2 *and* N_2	6.4	158	98

Heat Capacity and Entropy

The molecular constants are based on emission spectra of the $^3\Pi$–$^3\Pi$ transition otained by Douglas and Herzberg.[1] Observations of the same triplet in absorption by Thrush[5] strongly suggests that the ground state of BN is $^3\Pi$ in contrast to $^1\Sigma$ as observed for the isoelectronic molecules BeO and C_2. Electronic levels for the $^3\Pi$ states are taken from Douglas and Herzberg[1] while values for $^1\Sigma^+$ and $^1\Pi$ have been estimated from the SCF calculations of Masse and Barlochter.[6]

PREVIOUS: June1966 (1 atm) CURRENT: June 1966 (1 bar)

$S°(298.15\ K) = 73.538 \pm 0.08\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1240 \pm 2\ K$

$\Delta_f H°(0\ K) = -971.0 \pm 2.5\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -975.7 \pm 2.1\ kJ·mol^{-1}$
$\Delta_{fus} H° = 33.47 \pm 2.0\ kJ·mol^{-1}$

Enthalpy of Formation

Adami and Joe[1] measured enthalpies of solution of B_2O_3(cr), NaCl(cr) and $NaBO_2$(cr) in aqueous HCl solution and derived $\Delta_f H°(298.15\ K) = -12.43 \pm 0.1$ kcal·mol^{-1} for $NaBO_2$(cr) + HCl(12.732 H_2O, aq) → NaCl(cr) + 1/2 B_2O_3(cr) + 1/2 H_2O(l) which leads to $\Delta_f H°(NaBO_2$, cr, 298.15 K) = -233.2 ± 0.6 kcal·mol^{-1} using JANAF auxiliary data.[2] This value is adopted.

Grenier and White[3] measured the enthalpy of solution of crystal $Na_2OB_2O_3$ in 2N nitric acid solution at 0°C as -20.43 ± 0.36 kcal·mol^{-1}. Since the correction term for $\Delta_{sol}H°$ from 0° to 25°C is generally small, we may assume the enthalpy of solution is the same at 0°C as at 25°C within the uncertainty of ±1 kcal·mol^{-1}. Thus we obtain $\Delta_{sol}H°(25°C) = -10.22 \pm 1$ kcal·mol^{-1} for $NaBO_2$(cr) + HNO_3(27.75 H_2O, aq) + H_2O(l) → $NaNO_3$(27.75 H_2O, aq) + H_3BO_3(27.75 H_2O, aq) from which we derived $\Delta_f H°(NaBO_2$, cr, 298.15 K) = -234.7 ± 1.5 kcal·mol^{-1} based on JANAF auxiliary data.[4]

Shartsis and Capps[5] measured the heats of solution in 2N nitric acid of various Na_2O–B_2O_3 glass and crystalline mixtures containing 1.0–38.7 mole % of Na_2O. When their data are extrapolated to 50 mole %, we obtain $\Delta_{sol}H°(25°C) = -11.5 \pm 1.5$ kcal·mol^{-1} for the same reaction as given before. The derived enthalpy of formation is -233.4 ± 1.5 kcal·mol^{-1} which is in good agreement with the value adopted.

Heat Capacity and Entropy

Grenier and Westrum[6] measured low temperature heat capacities from 5 to 346 K. The adopted C_p are derived from their experimental heat capacities by a polynomial curve fitting technique. The derived entropy, $S°(298.15\ K)$, is 17.576 ± 0.02 cal·K^{-1}·mol^{-1} based on $S° = 0.001$ cal·K^{-1}·mol^{-1} at 5.48 K. Pankratz[7] measured high temperature enthalpy data by drop calorimetry in the temperature range 404–1200.3 K. We adopt the smooth C_p derived by Pankratz. The average deviation of the observed enthalpy data from the adopted values is about 0.1%.

Fusion Data

Our analysis of several sets of binary phase data[8–10] yields the enthalpy of fusion, $\Delta_{fus}H° = 8.0 \pm 0.5$ kcal·mol^{-1}. Petit and Jaeger[11] derived $\Delta_{fus}H°(1239\ K) = 8.0$ kcal·mol^{-1} from their phase data for the $NaBO_2$–NaF system. The adopted melting point (1240 K) is obtained from Pankratz.[7] Literature value include 1239 K,[8–12] 1238 K[13] and 1237 K.[14]

PREVIOUS: March 1965 CURRENT: June 1971

$S°(298.15\ K) = [82.958]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1240 \pm 2\ K$

$\Delta_f H°(298.15\ K) = [-960.019]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 33.47 \pm 2.0\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(NaBO_2, l, 298.15\ K)$ is calculated from that of the crystal by adding $\Delta_{fus} H°$ and the difference in enthalpy, $H°(1240\ K)–H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The constant heat capacity of the liquid is estimated to be 35 $cal·K^{-1}·mol^{-1}$ based on that of $LiBO_2$(l), 34.491 $cal·K^{-1}·mol^{-1}$,[1] which was derived from high temperature enthalpy measurements. A glass transition is assumed at 826 K below which the heat capacities are assumed to be the same as the crystal.

$S°(NaBO_2, l, 298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

See the crystal table for details.

Vaporization Data

The boiling point is calculated as the temperature at which the fugacity is 1 bar for the reaction $NaBO_2(l) \rightarrow NaBO_2(g)$. The enthalpy of vaporization is the difference in $\Delta_f H°$ at the boiling point between liquid and gas.

Enthalpy of Formation

Jensen[1] determined equilibrium constants for the reaction: $Na(g) + HBO_2(g) \rightarrow NaBO_2(g) + H(g)$ by flame studies. This technique involved several assumptions, the most basic of which was that boron added to $H_2/N_2/O_2$ flames was converted completely to HBO_2. The hydrogen atom concentration was taken from previous studies on such flames. Sodium metaborate was assumed to be formed in the flame. The concentration of Na atom was determined by atomic absorption spectrophotometry. JANAF 3rd law analysis of his equilibrium constant equation in the temperature range from 2000 to 2600 K yields $\Delta_f H(298.15\ K) = 7.55 \pm 1.08\ kcal \cdot mol^{-1}$ and the drift $2.50\ cal \cdot K^{-1} \cdot mol^{-1}$. (The 2nd law enthalpy of reaction is $\Delta_r H°(298.15\ K) = 1.81\ kcal \cdot mol^{-1}$.) Using the 3rd law $\Delta_r H°(298.15\ K)$ and JANAF auxiliary data, we obtain $\Delta_f H°(NaBO_2, g, 298.15\ K) = -152.8\ kcal \cdot mol^{-1}$. The uncertainty in this result is about $\pm 6\ kcal \cdot mol^{-1}$.

Buchler and Berkowitz–Mattuck[2] studied mass spectrometrically the sublimation of sodium metaborate and obtained $\Delta_{sub} H°(1070\ K) = 73 \pm 3\ kcal \cdot mol^{-1}$ for $NaBO_2(cr) \rightarrow NaBO_2(g)$ by a 2nd law method. JANAF reduction to 298.15 K gives $\Delta_{sub} H°(298.15\ K) = 76.6 \pm 3\ kcal \cdot mol^{-1}$ which leads to $\Delta_f H°(298.15\ K)(NaBO_2, g) = -156.6 \pm 3\ kcal \cdot mol^{-1}$. They also determined the vapor pressure of $NaBO_2$ at 1070 K as 5×10^{-7} atm by comparison with the vapor pressure of silver. JANAF 3rd law analysis of this single vapor pressure point gives $\Delta_{sub} H°(298.15\ K) = 83.37\ kcal \cdot mol^{-1}$ which leads to $\Delta_f H°(NaBO_2, g, 298.15\ K) = -149.8\ kcal \cdot mol^{-1}$.

Cole and Taylor[3] determined the vapor pressures of $NaBO_2(g)$ by a dynamic method with dry N_2 as carrier gas. Their vapor pressure data were taken over a flow–rate range where the apparent vapor pressure increased with decreasing flow rate, and the data were then extrapolated to zero flow rate. The vapor species of the sample was also assumed to be monomeric $NaBO_2(g)$. JANAF 3rd law analyses of their reported vapor pressure data over the liquid $NaBO_2$ in the temperature range 1150°C–1350°C yield $\Delta_{vap} H°(298.15\ K) = 75.37 \pm 3.32\ kcal \cdot mol^{-1}$ and the drift $-20.6\ cal \cdot K^{-1} \cdot mol^{-1}$. (The 2nd law enthalpy of vaporization is $\Delta_{vap} H°(298.15\ K) = 107\ kcal \cdot mol^{-1}$). Using the 3rd law $\Delta_{vap} H°(298.15\ K)$, we obtain $\Delta_f H°(298.15\ K) = -154.1 \pm 4\ kcal \cdot mol^{-1}$.

A weighted average, $\Delta_f H°(NaBO_2, g, 298.15\ K) = -155 \pm 3\ kcal \cdot mol^{-1}$, is adopted in the tabulation.

Heat Capacity and Entropy

The adopted vibrational frequencies are obtained from Seshadri *et al.*,[4] who observed the infrared spectra of $NaBO_2$ in an argon matrix and made a complete assignment of all six fundamentals. The uncertainty of the calculated statistical entropy at 298.15 K is estimated to be $\pm 1\ cal \cdot mol^{-1}\ K^{-1}$ which is due to the magnitude of the matrix shifts from the free molecule spectrum, particularly for the lower frequency modes.

Buchler and Marran[5] observed only two vibrational frequencies, 1935 and 600 cm^{-1}, in their gas–phase infrared spectra. These two frequencies are in reasonable agreement with those reported by Seshadri.[4]

By electron diffraction studies, Akishin and Spiridonov[6] determined the molecular structure of gaseous sodium metaborate and found the bond length and angles which are adopted in the tabulation. The angle Na–O–B is taken as 90° based on that of $LiBO_2(g)$.[7]

The three principal moments of inertia are $I_A = 5.1904 \times 10^{-39}$, $I_B = 19.0974 \times 10^{-39}$, and $I_C = 24.2878 \times 10^{-39}\ g \cdot cm^2$.

Enthalpy of Formation

The enthalpy of formation has recently been determined by several workers whose values are in close agreement. Blackburn, *et al.*[1] measured the ion currents corresponding to BO^+ and $B_2O_2^+$ as a function of temperature in a mass spectrometer. From a least squares fit of the data they report $\Delta H = 56.6 \pm 1.8\ kcal \cdot mol^{-1}$ for the reaction $1/2B_2O_2(g) \rightarrow BO(g)$; this yields $\Delta_f H°(BO, g, 298.15\ K) = 2.1 \pm 2.8\ kcal \cdot mol^{-1}$ using $\Delta_f H°(B_2O_2, g, 298.15\ K) = -109 \pm 2\ kcal \cdot mol^{-1}$.

De Galan, *et al.*[2] from flame photometric measurements reports $D_0°(BO) = 8.3eV(191.4\ kcal \cdot mol^{-1})$, which corresponds to $\Delta_f H°(BO, g, 298.15\ K) = -0.1\ kcal \cdot mol^{-1}$.

Coppens, *et al.*[3] from a mass spectometric study of several isomolecular exchange reactions, conclude that $D_0°(BO) = 8.29 \pm 0.1$ eV$(191.2 \pm 2.3\ kcal \cdot mol^{-1})$ or $\Delta_f H°(BO, g, 298.15\ K) = 0.1 \pm 2.3\ kcal \cdot mol^{-1}$.

Farber, *et al.*[4] investigated the same reaction as Blackburn *et al.* and reported $\Delta_f H°(1800\ K) = 53.8 \pm 1.9\ kcal \cdot mol^{-1}$, which yields $\Delta_f H°(BO, g, 298.15\ K) = 0.9 \pm 2.9\ kcal \cdot mol^{-1}$.

We adopt a median value of $0 \pm 2\ kcal \cdot mol^{-1}$ which includes all the determinations

Heat Capacity and Entropy

The molecular and vibrational constants for the ground state are from Herzberg.[5] The electronic levels are also given by Herzberg with the exception of the level at 39957, the $A^2\Sigma$ level designated B' by Mal'tsev and Kataev.[6] The molecular constants were all adjusted to reflect normal isotopic abundancies.

Enthalpy of Formation

Greene[1] measured the vapor pressure of B_2O_3 and examined the infrared absorption spectra of B_2O_3, B_2O_2 and BO_2. The isotope shift and oxygen and temperature dependencies of the boric acid fluctuation bands were studied. The enthalpy change, $\Delta_r H°(2100\ K) = 76 \pm 2$ kcal·mol^{-1}, for the reaction 1/2 B_2O_3(l) + 1/4 O_2(g) = BO_2(g), was obtained spectroscopically. Based on this data and $\Delta_f H°(B_2O_3, l, 2100\ K) = -291.05$ kcal·mol^{-1}, we derive $\Delta_f H°(BO_2, g, 298.15\ K) = -68.4 \pm 2$ kcal·mol^{-1}.

Rusin[2] determined the equilibrium constant of the reaction $HBO_2(g) + OH(g) = BO_2(g) + H_2O(g)$ by simultaneously recording the pressure and spectra at 3000–3200 K of HBO_2 and BO_2, which were produced from the combustion in a bomb of mixtures of H, O, CO and a small amount of B_2H_6. Using the experimental value $K_p(3100\ K) = 0.9$, and JANAF Gibbs energy functions for the reactants and products, we obtain $\Delta_r H°(298.15\ K) = 0.53$ kcal·mol^{-1} for that reaction. Employing $\Delta_f H°(298.15\ K) = -134.00$, 9.43 and −57.80 kcal·mol^{-1} for HBO_2(g), OH(g) and H_2O(g), respectively, we derive the value $\Delta_f H°(BO_2, g, 298.15\ K) = -66.24$ kcal·mol^{-1}.

In a study of gases from flames containing trimethylborate stabilized on flat porous metal burners, Kaskan[3] obtained data consistent with the bands being due to the molecule BO_2(g). The temperature dependence of the equilibrium constants for the reaction $OH(g) + HBO_2(g) = H_2O(g) + BO_2(g)$ was investigated and the data were reported to be consistent with a value $\Delta_r H°(1800\ K) = -16$ kcal·mol^{-1}. Based on this $\Delta_r H°(1800\ K)$ value, we calculate $\Delta_f H°(BO_2, g, 298.15\ K) = -83.62$ kcal·mol^{-1}. Kaskan[4] has studied the effect of oxygen on the intensity of absorption (5470 Å) in the green or "fluctuation" bands of the gas phase in equilibrium with B_2O_3(l). At constant temperature the absorptivity was found to depend on the 1/4 power of the oxygen pressure. This is interpreted as evidence that the absorbing species is BO_2(g). The reaction 1/2 B_2O_3(l) + 1/4 O_2(g) = BO_2(g) was found to be 70 kcal·mol^{-1} endothermic in the temperature range 1660–1950 K, yielding $\Delta_f H°(BO_2, g, 298.15\ K) = -75.28$ kcal·mol^{-1}. Rusin *et al.*[2] discussed the discrepancy between their results and those of the above two investigations and commented that the results of Kaskan[3,4] were derived based on the assumption that Beer's law was obeyed over the temperature range 1400–2200 K. Actually, the relative population α of the principal electronic state $X^2\Pi$ of the BO_2 molecule changes greatly over this temperature range. Therefore the expression for the dependence of the optical density on the concentration of BO_2 must be corrected to allow for the variation of α with temperature.

The enthalpy of formation of BO_2(g) at 298.15 K is selected as -68 ± 2 kcal·mol^{-1}.

Heat Capacity and Entropy

The electronic levels and quantum weights are obtained from Johns.[5] Vibrational frequencies, bond distance and rotational constant were reported by Johns,[5] Sommer,[6] and Snowden.[7] The values adopted are those determined by Snowden.[7] Snowden used a (1:1) mixture of KBF_4 and B_2O_3 placed in a 13 mm Vycor tube. The mixture was heated to produce a vapor which passed through an external electrodeless discharge. The intense emission spectrum of the BO_2 molecule was observed. The fluorescence spectrum obtained by Johns was too weak for a full characterization of the electronic ground state.

Enthalpy of Formation

Jensen[4] has obtained equilibrium constants for the reaction $HBO_2 + e^- \rightarrow H + BO_2^-$. This involves several assumptions the most basic of which is that boron added to $H_2/N_2/O_2$ flames is converted completely to HBO_2. The free electrons are produced by addition of potassium to the flame, and their concentration is measured directly by a microwave cavity resonance method. The hydrogen atom concentration is taken from previous studies on such flames. The BO_2^- concentration is obtained from the difference between the K^+ concentration and the free electron measurement. The K^+ concentration is measured by an electrostatic probe.

By 2nd and 3rd analysis of the data, 11 points read back from a plot, we obtain $\Delta_f H°$(II, 298.15 K) = 27.5 ± 4 $kcal·mol^{-1}$ and $\Delta_f H°$ (III, 298.15 K) = 20 ± 2 $kcal·mol^{-1}$ with a drift of -3.7 ± 1.5 $cal·K^{-1}·mol^{-1}$. The 3rd law value yields $\Delta_f H°(BO_2^-, 298.15\ K) = -166 \pm 6$ $kcal·mol^{-1}$ where the uncertainty includes possible errors in the functions. This corresponds to an electron affinity of BO_2 equal to 98 ± 6 $kcal·mol^{-1}$ (4.25 eV).

Heat Capacity and Entropy

The molecular structure is assumed to be linear using the Walsh[1] prediction for 16 valence electron XY_2 molecules. The electronic states are taken from those for CO_2(g) (2), which is isoelectronic with BO_2^- (g). The electronic level 35000 cm^{-1} and vibrational frequencies are estimated by comparison with the corresponding values for CO_2, CO_2^+, and BO_2, and, the data of Vasco and Srb[3] on the BO_2^- ion in alkali halide lattices. The B–O bond distance in BO_2^-(g) is assumed to be smaller than the B–O bond in BO_2(g), because the BO_2^-(g) molecule has one more bonding electron than the BO_2(g) molecule.

Enthalpy of Formation

Gingerich,[1] empolying mass spectrometric investigations of the Au–Ce–CeS–BN–C system from a tungsten Knudsen effusion cell, reports two values of the BS(g) dissociation energy. The reaction enthalplies were evaluated by the 3rd law method. The two values reported are 140.4 ± 6.0 kcal·mol^{-1}, based on the dissociation energy of CS(g), and 145.4 ± 6.0 kcal·mol^{-1}, based on the dissociation energy of CeS(g).

Uy and Drowart[2] also studied the dissociation energy of BS(g) by two different exchange reactions using mass spectrometric Knudsen cell techniques. Molybdenum cells were used. Based on an exchange between B(g) and YS(g), they reported D_0° = 138.8 ± 3.2 kcal·mol^{-1} for BS(g). A second determination based on an exchange between BO(g) and YS(g) was reported as D_0° = 137.0 ± 3.2 kcal·mol^{-1}

Gaydon[3] suggests a value of 118 kcal·mol^{-1} for the dissociation energy based on two linear Birge–Sponer extrapolations from the data of Zeeman.[4] This data gave values of 154.5 kcal·mol^{-1} and 131.4 kcal·mol^{-1} for extrapolations from the ground state and $A^2\Pi$ state, respectively. McDonald and Innes[5] extended Zeeman's analysis,[4] examined perturbative effects, and calculated $\omega_e y_e = -0.004\ cm^{-1}$ for the ground state. This perturbative interpretation was supported by Singh, Tewari, and Mohan.[7] Accounting for $\omega_e y_e$ value, the Birge–Sponer extrapolation yields a value D_0° = 142.3 kcal·mol^{-1} for BS(g). This value was adjusted to 140.0 kcal·mol^{-1} using an ionic character correction factor as suggested by Hildenbrand and Murad.[6]

The value of 140.0 ± 4.0 kcal·mol^{-1} for the dissociation energy of BS(g) is chosen as the best value. It is an average of the four reported thermochemical values and is the adjusted Birge–Sponer value, the adjustment arising from a correction technique which has been shown to be quite dependable. This value leads to a enthalpy of formation $\Delta_f H°(298.15\ K)$ = 58.1 ± 4.0 kcal·mol^{-1}.

Heat Capacity and Entropy

The spectroscopic constants for the $X^2\Sigma^+$ state are from Zeeman[4] and are corrected to account for the natural abundances of the elements. The electronic states X, A, and C are reported by Zeeman.[4] The $B^2\Sigma^+$ state is reported by McDonald and Innes.[5]

PREVIOUS: June 1972 (1 atm) CURRENT: June 1972 (1 bar)

$S°(298.15\ K) = [34.7 \pm 6.3]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{dcm} = [2500]\ K$

$\Delta_f H°(0\ K) =$ Unknown
$\Delta_f H°(298.15\ K) = -160.2 \pm 38\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Schissel and Trulson[1] used a mass spectrometer with Knudsen cells to study the vaporization of the titanium–boron system and obtained $\Delta_r G°(2340\ K) = -118.54\ kcal \cdot mol^{-1}$ for the reaction TiB(c) = Ti(g) + B(g). This corresponds to $\Delta_f G°(TiB, cr, 2340\ K) = -33.266 \pm 9\ kcal \cdot mol^{-1}$, where $4\ kcal \cdot mol^{-1}$ of the uncertainty is due to the enthalpy of sublimation of boron. When this is reduced to 298.15 K one obtains $\Delta_f H°(TiB, cr, 298.15\ K) = -38.3 \pm 9\ kcal \cdot mol^{-1}$. This value implies a high stability for TiB. This is also indicated by the phase studies of Nowotny *et al.*[2]

Heat Capacity and Entropy

The heat capacities fron 298 to 1200 K were estimated from that of TiB_2 by assuming the difference to be the same as that between CrB and CrB_2 as determined by R. Mezaki, E. W. Tilleux, D. W. Barnes and J. L. Margrave (Paper presented at the International Symposium on Nuclear Materials, Vienna, May 1962). A linear extrapolation was assumed above 1200 K.

The heat capacities above 298 K were also estimated from the relationship $C_p(Ti) + C_p(2B) - C_p(TiB_2) = 2/3\ [C_p(Ti) + C_p(B) - C_p(TiB)]$. This estimation agreed with the above to 4% over the temperature range 400 to 1000 K.

$S°(TiB, cr, 298.15\ K) = 8.3\ cal \cdot K^{-1} \cdot mol^{-1}$ was calculated by the method of Latimer.[3] Using JANAF $S°(TiB_2, cr, 298.15\ K) = 6.8\ cal^{-1}\ K^{-1} \cdot mol^{-1}$ and Latimer's value of $9.8\ cal \cdot K^{-1} \cdot mol^{-1}$ for the entropy contribution of Ti, an entropy contribution of $-1.5\ cal \cdot K^{-1} \cdot mol^{-1}$ per boron atom was calculated.

Decomposition Data

The phase diagram given by McQuillan and McQuillan[4] was used to estimate the decomposition temperature. This diagram shows the decomposition products are TiB_2 and Ti_2B. However, Nowotny *et al.*[2] have shown Ti_2B to be nonexistent and so the decomposition products are not defined; probably an eutectic of TiB and TiB_2 is involved.

Enthalpy of Formation

The equilbrium vapor pressure of the reaction $B_2(g) \rightarrow B(g) + B(cr)$ was determined by Verhaegen and Drowart.[5] Using the value, $p(B_2,g)/p(B,g) = 9 \times 10^{-5}$ at 2330 K where p is partial pressure, the enthalpy of reaction, $\Delta_r H°(298.15\ K)$, was evaluated by the 3rd law method to be -64.5 ± 5.0 kcal·mol^{-1}. Using auxiliary data,[6] this leads to $\Delta_f H°(298.15\ K) = 198.3 \pm 8.0$ kcal·mol^{-1} for $B_2(g)$ or $D_0° = 2.97 \pm 0.61$ eV.

Heat Capacity and Entropy

The thermodynamic functions are calculated using first order anharmonic corrections to Q_t^i and Q_v^i in the partition function $Q = Q_t \Sigma Q_t^i Q_v^i g_i \exp(-c_2\epsilon_i/T)$. Molecular and spectroscopic constants for the $^3\Sigma_g^-$ ground state and the $2^3\Sigma_u^-$ state are taken from a study[3] which revises the values of Douglas and Herzberg.[1,2] The molecular constants and electronic levels for the lowest $^5\Sigma_u^-$ state and $1^3\Sigma_u^-$ state are based on the ab initio configuration interaction calculations of Dupuis and Liu.[4] These calculations, along with the optical absorption and ESR spectra of B_2 at 4 K reported by Graham and Weltner,[7] support a $^3\Sigma_g^-$ ground state rather than $^5\Sigma_u^-$ favored by previous ab initio work.[8,9] All molecular and spectroscopic constants have been corrected to the average isotopic species.

Differences between our calculated thermodynamic functions and those given by Feber and Herrick[10] using direct summation techniques can be attributed to inclusion of the low lying $^5\Sigma_u^-$ state and $1^3\Sigma_u^-$ state in our calculations. The JANAF adopted entropy is 0.35–1.6 cal·K^{-1}·mol^{-1} higher than their values in the 500–600 K temperature range. The JANAF adopted heat capacities are also higher in the low temperature range, 0.2–0.9 cal·K^{-1}·mol^{-1} larger between 298–1000 K. A comparison of the thermodynamic functions calculated using only the ground and upper $2^3\Sigma_u^-$ state shows no major numerical difference with this earlier tabulation,[10] however.

Ground State Quantum Weight: [1] $\sigma = 2$

Point Point: [C_{2h}]

Bond Distances: Be–O = [1.63] Å; O–B = [1.34] Å; B=O = [1.20] Å

Bond Angles: O=B–O = [180]°; O–Be–O = [180]°; B–O–Be = [95]°

Product of the Moments of Inertia: $I_A I_B I_C = [5.382534 \times 10^{-113}]\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation was obtained from mass spectrometric studies; the following reactions at 1500 K were reported by Blackburn and Buchler.[1]

Reaction	$\Delta_r H°$, $kcal·mol^{-1}$
1. $B_2O_3(l) \rightarrow B_2O_3(g)$	$\Delta H_1 = 92.226$
2. $1/3\ Be_3B_2O_6(cr) + 2/3\ B_2O_3(l) \rightarrow Be(BO_2)_2(g)$	$\Delta H_2 = 118 \pm 2$
3. $Be_3B_2O_6(cr) \rightarrow 3\ BeO(cr) + B_2O_3(g)$	$\Delta H_3 = 112 \pm 1$
4. $Be_3B_2O_6(cr) \rightarrow 2\ BeO(cr) + Be(BO_2)_2(g)$	$\Delta H_4 = 137 \pm 3$
5. $3\ BeO(cr) + B_2O_3(l) \rightarrow Be_3B_2O_6(cr)$	$\Delta H_5 = 23$
6. $BeO(cr) + B_2O_3(g) \rightarrow Be(BO_2)_2(g)$	$\Delta H_6 = 22$

ΔH_1 was obtained from JANAF values[2] for $B_2O_3(l)$ and $B_2O_3(g)$. The values for ΔH_2, ΔH_3, and ΔH_4 were obtained from Blackburn and Buchler.[1] ΔH_5 was obtained by taking the average of $\Delta H_5 = -20$ $kcal·mol^{-1}$ in a weight loss experiment, $\Delta H_5 = \Delta H_1 - \Delta H_3 = -19.774$ $kcal·mol^{-1}$, and $\Delta H_5 = 3/2\ (\Delta H_2 - \Delta H_4) = 28.5$ $kcal·mol^{-1}$. The ΔH_6 value was obtained by taking the average of $\Delta H_6 = \Delta H_4 - \Delta H_3 = 25$ $kcal·mol^{-1}$ and $\Delta H_6 = \Delta H_2 - \Delta H_1 + 1/3\ \Delta H_5 = 18.107$ $kcal·mol^{-1}$. The $\Delta_f H°(298.15\ K)$ of BeB_2O_4 was calculated from reaction 6 with auxiliary JANAF values.

Heat Capacity and Entropy

The vibrational frequencies estimated by comparison with B_2O_3 were adjusted to obtain an $S°(1500\ K) = 127$ obtained in a manner analogous with $\Delta_f H°$ from the report of Blackburn and Buchler.[1] The frequencies listed are not in point group order. All other molecular constants were estimated by comparison with related boron oxide molecules. The principal moments of inertia are $I_A = 8.5573 \times 10^{-39}$, $I_B = 75.1462 \times 10^{-39}$, and $I_C = 83.7035 \times 10^{-39}$ $g·cm^2$.

$S°(298.15\ K) = [100 \pm 13]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 1768 \pm 5\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -3104 \pm 8\ kJ \cdot mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

The adopted $\Delta_f H°(298.15\ K) = -741.96 \pm 2\ kcal \cdot mol^{-1}$ was calculated from $\Delta_r H°(298.15\ K) = -13.38 \pm 0.5\ kcal \cdot mol^{-1}$ for $3BeO(cr) + B_2O_3(g, l) = Be_3B_2O_6(cr)$ measured calorimetrically by Gross.[1] From equilibrium data relating to the same reaction at 1500 K, Blackburn and Buchler[2] report enthalpies of reaction of -21 ± 2 and $-28.5 \pm 5\ kcal \cdot mol^{-1}$ which correspond to -21.7 and $-29.2\ kcal \cdot mol^{-1}$ at 298.15 K. The discrepancy of 8 to 16 $kcal \cdot mol^{-1}$ is attributed primarily to the equilibrium values. These values result from differences between 2nd law enthalpies of reaction derived from the variation with temperature of ion intensities for $B_2O_3^+$ and $Be(BO_2)_2^+$, respectively, over the systems $B_2O_3(l)$–$Be_3B_2O_6(cr)$ and $Be_3B_2O_6(cr)$–BeO(cr). The reported reactions and their heats are:

Reaction	$\Delta_r H°(1500\ K)$ $kcal \cdot mol^{-1}$
(a) $B_2O_3(l) \rightarrow B_2O_3(g)$	91 ± 0.5
(b) $Be_3B_2O_6(cr) \rightarrow 3\ BeO(cr) + B_2O_3(g)$	112 ± 1
(c) $1/3\ Be_3B_2O_6(cr) + 2/3\ B_2O_3(l) \rightarrow Be(BO_2)(g)$	118 ± 2
(d) $Be_3B_2O_6(cr) \rightarrow 2\ BeO(cr) + Be(BO_2)_2(g)$	137 ± 3

Heat Capacity and Entropy

The heat capacity was estimated from that for BeO(cr) and B_2O_3(cr). The adopted $S°(298.15\ K) = 24 \pm 3$ eu is an average value from the following three estimates. Blackburn and Buchler[2] report $K_p = 2.7 \times 10^{-5}$ atm and 9.3×10^{-6} atm at 1500 K for reactions a and b (see enthalpy of formation), based on vacuum balance data and ion intensities, respectively. Three K_p's yield $\Delta_r G°(1500\ K) = -3.17\ kcal \cdot mol^{-1}$ for $3\ BeO(cr) + B_2O_3(l) \rightarrow Be_3B_2O_6(cr)$. Combining this with the JANAF value for $\Delta_r H°(1500\ K) = -12.64\ kcal \cdot mol^{-1}$, we get $\Delta_r S°(1500\ K) = -6.3$ and $S°(Be_3B_2O_6, cr, 298.15\ K) = 22.9\ cal \cdot K^{-1} \cdot mol^{-1}$. This entropy agrees with 23 $cal \cdot K^{-1} \cdot mol^{-1}$ estimated from the sum of entropies for the component oxides; however, the entropy for $Ca_3B_2O_6(cr)$ observed by Kelley *et al.*[3] is larger than that of the component oxides by 2.5 $cal \cdot K^{-1} \cdot mol^{-1}$. Use of this increment leads to 25.5 $cal \cdot K^{-1} \cdot mol^{-1}$ for $Be_3B_2O_6(cr)$.

Fusion Data

T_{fus} was obtained from Blackburn and Buchler.[2]

Ground State Quantum Weight: 1 $\sigma = 4$

Point Group: D_{2d}

Bond Distances: B–Cl = 1.73 ± 0.02 Å; B–B = 1.75 ± 0.01 Å

Bond Angles: Cl–B–Cl = 120 ± 2°

Dihedral angle between two BCl_2 planes = 90°

Product of the Moments of Inertia: $I_A I_B I_C = 5.336257 \times 10^{-112}\ g^3·cm^6$

Enthalpy of Formation

Gunn *et al.*[1] determined the enthalpy change ($\Delta_r H°$) of the reaction $B_2Cl_4(l) + Cl_2(g) = 2\ BCl_3(g)$. From the value, $\Delta_r H°(298.15\ K) = 67.3 \pm 0.6\ kcal·mol^{-1}$, the enthalpy of formation for $B_2Cl_4(l)$ was calculated as $125.32 \pm 1.20\ kcal·mol^{-1}$. Based on $\Delta_{vap} H°(338.7\ K) = 8.029\ kcal·mol^{-1}$ reported by Urry *et al.*,[2] the enthalpy of formation for $B_2Cl_4(g)$ was derived to be $116.9 \pm 1.2\ kcal·mol^{-1}$.

Heat Capacity and Entropy

The vibrational frequencies, molecular structure and constants were taken from Mann and Fano.[3] The barrier restricting internal rotation about the B–B single bond is fixed at 1.53 ± 0.60 $kcal·mol^{-1}$ obtained from Mason and Kreevoy.[4] The reduced moment of inertia for BCl_2 top is $I_r = 13.2149 \times 10^{-39}\ g·cm^2$. The principal moments of inertia are: $I_A = 52.8594 \times 10^{-39}$, $I_B = I_C = 100.4748 \times 10^{-39}\ g·cm^2$.

Ground State Quantum Weight: 1 $\sigma = 4$
Point Group: D_{2d}
Bond Distances: B–B = 1.67 Å; B–F = 1.32 Å
Bond Angles: F–B–F = 120°; F–B–B = 120°
Dihedral angle between two BF_2 planes = 90°
Product of the Moments of Inertia: $I_A I_B I_C = 2.502146 \times 10^{-113}$ $g^3·cm^6$

Enthalpy of Formation

The enthalpy of formation was calculated based on the value, $\Delta_f H° = -82.0 \pm 1.0$ $kcal·mol^{-1}$ for the reaction $B_2F_4(g) + Cl_2(g) = 0.92\ BF_3(g) + 0.46\ BF_2Cl(g) + 0.32\ BFCl_2(g) + 0.30\ BCl_3(g)$ reported by Gunn and Green.[1]

Heat Capacity and Entropy

The molecular and spectroscopic constants were obtained from Gayles and Self.[2] The vibrational frequencies were corrected to the average isotropic species. The molecular configuration was reported to be staggered, analogous to that observed for B_2Cl_4(g). The angle between two $B–BF_2$ planes is approximately 90°. The thermodynamic functions were evaluated based on an assumption that there is free rotation at the B–B bond. The reduced moment of inertia for the BF_2 top is $I_r = 4.1231 \times 10^{-39}$ $g·cm^2$. The principal moments of inertia are: $I_A = 16.4908 \times 10^{-39}$. $I_B = I_C = 38.9529 \times 10^{-39}$ $g·cm^2$.

Ground State Quantum Weight: 1 $\sigma = 4$

Point Group: D_{2h}

Bond Distances: B–O = [1.4] Å; B–F = [1.32] Å

Bond Angles: B–O–B = [180]°; F–B–F = [120]°

Dihedral angle between the two BF_2 planes = 90°

Product of the Moments of Inertia: $I_A I_B I_C = [7.701231 \times 10^{-113}]\ g^3·cm^6$

Enthalpy of Formation

Bidinosti and Coatsworth[1] have reported $\Delta_f H°(1100\ K) = 18.5 \pm 3$ kcal·mol^{-1} for the reaction 4 $BF_3(g) + B_2O_3(l) = 3\ B_2OF_4(g)$. This value was obtained from a mass spectrometric study of the variation of the ion intensities with temperature of the BF_3^+ and $B_2OF_4^+$ species. Employing JANAF auxiliary values[2] we obtain $\Delta_f H°(B_2F_4O, g, 1100\ K) = -455.75 \pm 2$ kcal·mol^{-1} which reduces to $\Delta_f H°(298.15\ K) = -453.65 \pm 2$ kcal·mol^{-1}.

Heat Capacity and Entropy

By analogy with $B_2F_4(g)$[3] free rotation of the BF_2 groups is assumed. Because of the large separation of the two BF_2 groups the molecule is considered to be planar. The B–O distance is assumed to be that in $BF_2O(g)$[2] and the B–F distance that in $B_2F_4(g)$.[2] The vibrational frequencies are estimated by comparison with those for B_2F_4;[3] the values are given above in the order $3A_g$, A_u, $2B_{1g}$, $2B_{1u}$, B_{2g}, $3B_{2u}$, $3B_{3u}$. The thermodynamic functions were evaluated based on an assumption that there is free rotation at the two B–O bonds. The reduced moment of inertia for the BF_2 top is $I_r = 4.1227 \times 10^{-39}$ g·cm^2. The principal moments of inertia are: $I_A = 16.4908 \times 10^{-39}$, $I_B = 60.5877 \times 10^{-39}$, and $I_C = 77.0785 \times 10^{-39}$ g·cm^2.

$S°(298.15\ K) = [126 \pm 4]\ J \cdot K^{-1} \cdot mol^{-1}$
T_{fus} = Unknown

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -1410 \pm 8\ kJ \cdot mol^{-1}$
$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

The enthalpy change, $\Delta_f H°(298.15\ K) = -91.3 \pm 1$ kcal·mol^{-1}, for the reaction $B_2(OH)_4$(cr) + (m + 2)$AgNO_3$(aq) + (n + 2) H_2O(l) = 2 Ag(cr) + [2 H_3BO_3 + 2 HNO_3 + m$AgNO_3$]nH_2O(aq) was determined electrically by Finch *et al.*[1] The enthalpy of formation of $B_2(OH)_4$(cr) was reported to be −335.1 kcal·mol^{-1}. This value was corrected to be 337.1 ± 2 kcal·mol^{-1} by use of more recent data on the $\Delta_f H°(298.15\ K)$ values used for calculation.

Heat Capacity and Entropy

The heat capacity for $B_2(OH)_4$(cr) was estimated by comparison with those for $B(OH)_3$(cr). $S°(298.15\ K)$ was calculated based on 3 cal·K^{-1}·mol^{-1} per atom for $B_2(OH)_4$(cr), which was obtained from the corresponding values for HBO_2(cr) and $B(OH)_3$(cr).

Sublimation Data

The value, $\Delta_{sub} H°(298.15\ K)$, was as the difference between $\Delta_f H°(298.15\ K)$ for $B_2(OH)_4$(g) and $B_2(OH)_4$(cr).

Dihedral angle between two $B(OH)_2$ planes = 90°

Product of the Moments of Inertia: $I_A I_B I_C$ = [2.299983 × 10^{-113}] $g^3 \cdot cm^6$

Enthalpy of Formation

The enthalpy of formation, $\Delta_f H°(B_2(OH)_4, g, 298.15\ K)$, is calculated using bond energies, $D°_0$(B–OH) = 132 and $D°_0$(B–B) = 78 $kcal \cdot mol^{-1}$. The bond energy $D°_0$(B–OH) was taken from that in $B(OH)_3$(g) and $D°_0$(B–B) was estimated by comparison with that in B_2F_4(g).

Heat Capacity and Entropy

The molecular structure was assumed to be the same as that for B_2F_4(g), i.e. the two $B(OH)_2$ units have staggered configuration, and free rotation about B–B bond. The B–B bond distance was taken as that in B_2F_4 molecule. Those for B–O and B–H bond and bond angles were adopted from H_3BO_3 molecule. Eleven vibratonal frequencies were assumed to be the same as those for B_2F_4(g). In addition to these were added four OH torsion frequencies, 824(2) and 209(2), four OH stretching, 3200(4), and four B–O–H bending frequencies, 1200(2) and 880(2). The thermodynamic functions were evaluated based on an assumption that there is free rotation at the B–B bond. The reduced moment of inertia for the $B(OH)_2$ top is I_r = 4.1012 × 10^{-39} $g \cdot cm^{-2}$. The principal moments of inertia are: I_A = 16.4048 × 10^{-39}, I_B = 37.4430 × 10^{-39}, and I_C = 37.4441 × 10^{-39} $g \cdot cm^2$.

Ground State Quantum Weight: [1] $\sigma = 4$
Point Group: D_{2h}
Bond Distances: B–B = 1.775 ± 0.004 Å; B–H_t = 1.196 ± 0.016 Å; B–H_b = 1.339 ± 0.013 Å
H_t = terminal hydrogen, H_b = bridge hydrogens.
Bond Angles: H_t–B–H_t = 120.2 ± 1.6°
Product of the Moments of Inertia: $I_A I_B I_C = 2.459830 \times 10^{-116}\ g^3·cm^6$

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ is a weighted average of the following data. The older data of Roth *et al.*[8] deviates from the rest of the investigations and is not included.

Source	Reaction	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}
1	$B_2H_6(g) \rightarrow 2\ B(am) + 3\ H_2(g)$	−5.0	7.4
2	$B_2H_6(g) \rightarrow 2\ B(am) + 3\ H_2(g)$	−6.73	9.13
3	$B_2H_6(g) + 6\ Cl_2 \rightarrow 2\ BCl_3(g) + 6\ HCl(g)$	−342.3	17.3
4	$B_2H_6(g) + 6\ H_2O(l) + [2000\ H_2O](l) \rightarrow 2[H_3BO_3 + 1000\ H_2O](soln) + 6\ H_2(g)$	−111.46 ± 0.54	9.32
7a	$B_2H_6(g) + 2006\ H_2O \rightarrow 2(H_3BO_3 + 1000\ H_2O) + 6\ H_2(g)$	−112.22 ± 0.10	10.08
7b	$BCl_3(l) + 130.3\ H_2O \rightarrow (H_3BO_3 + 1000\ H_2O) + 3(HCl + 100\ H_2O)$	−68.14	—
(a) − 2(b) + (c)	$B_2H_6(g) + 6(HCl100\ H_2O) \rightarrow 2\ BCl(l) + 6\ H_2(g)$	+24.06	10.06
9	$(CH_3)_3\ N(g) + 1/2\ B_2H_6(g) \rightarrow (CH_3)_3N{:}BH_3(cr)$	−32.33 ± 0.06	8.3
13	$(CH_3)_3N(g) + 1/2\ B_2H_6(g) \rightarrow CH_3)_3N{:}BH_3(cr)$	−31.40	6.5

Sources of Auxiliary Data: From the JANAF tables, $\Delta_f H°(298.15\ K) = 1.2, -96.31, -22.063\ kcal·mol^{-1}$ of B(am), $BCl_3(g)$ and HCl(g), respectively. From Rossini,[11] the $\Delta_{vap}H°(298.15\ K) = 5.6\ kcal·mol^{-1}$ of BCl_3. From Wagman,[12] the $\Delta_f H°(298.15\ K)$ of (HCl + 1000 H_2O) = −39.657 $kcal·mol^{-1}$. From Good *et al.*,[5] the $\Delta_f H°(H_3BO_3, cr, 298.15\ K) = -261.47 \pm 0.20\ kcal·mol^{-1}$ and the H_3BO_3 solution data of Fasolino.[6] $\Delta_f H°((CH_3)_3N, g, 298.15\ K) = -5.9 \pm 0.4\ kcal·mol^{-1}$ from Jaffe.[10]

Heat Capacity and Entropy

The molecular constants reported by Carroll,[14] were selected. They agree well with those reported by Hedberg and Schomaker.[15] The principal moments of inertia are $I_A = 1.0562 \times 10^{-39}$, $I_B = 4.6381 \times 10^{-39}$, and $I_C = 5.0213 \times 10^{-39}\ g·cm^2$.

The vibrational frequencies for $B_2{}^{11}H_6$ were those listed by Wu[16] except for υ_8, υ_{10} and υ_{14} which were taken from the calculated frequency column of Table VIII–1 (page 55) of the Thesis.

$\Delta_f H°(0\ K) = -91.3 \pm 8.4\ kJ \cdot mol^{-1}$

$S°(298.15\ K) = 35.98 \pm 0.17\ J \cdot K^{-1} \cdot mol^{-1}$ $\Delta_f H°(298.15\ K) = -92.0 \pm 8.4\ kJ \cdot mol^{-1}$

T_{dcm} = [1320] K

Enthalpy of Formation

The equilibrium constants (993–1108 K) for the reaction 2 MgB_2(cr) = Mg(g) + MgB_4(cr) were determined by Wright and Walsh.[1] The corresponding 2nd and 3rd law values of $\Delta_f H°(298.15\ K)$ for this reaction were derived as 53.1 ± 4.7 and 54.1 kcal·mol^{-1}, respectively. Using the 3rd law value obtained, i.e., $\Delta_r H°(298.15\ K) = 54.1$ kcal·mol^{-1}, for the reaction, $\Delta_f H°(MgB_2, cr, 298.15\ K)$ was evaluated as −22.0 ± 2.0 kcal·mol^{-1}.

Heat Capacity and Entropy

The low temperature (21.12–304.22 K) heat capacities were measured by Swift and White.[2] Above 298.15 K, the values of C_p were estimated with those of other related borides. $S°(298.15\ K)$ was reported by Swift and White[2] using $S°(extrap, 20\ K) = 0.005$ cal·K^{-1}·mol^{-1}.

Decomposition Data

T_{dcm} was taken from Markovsky *et al.*[3] On heating to high temperatures, MgB_2(cr) decomposes into boride phases, A, B, and C with the separation of Mg. The composition of phase A is close to MgB_6 and that of C is close to MgB_{12}.

Enthalpy of Formation

The enthalpy of formation was calculated from the estimated enthalpy of reaction $\Delta_f H°(0\ K) = 300 \pm 25$ kcal·mol^{-1} for $B_2O(g) \rightarrow 2B(g) + O(g)$, using the JANAF auxiliary data[2] for B(g) and O(g). The value of $\Delta_f H°(0\ K)$ was assumed to be the sum of the enthalpies of dissociation, 120 kcal·mol^{-1} for $B_2O(g) \rightarrow BO(g) + B(g)$ and 180 kcal·mol^{-1} for $BO(g) \rightarrow B(g) + O(g)$. The former was estimated and the latter was derived from the JANAF values.[2]

The possible existence of $B_2O(g)$ in the burning of boron under reducing conditions was discussed by Bahn.[1] He estimated the enthalpy of formation to lie between −27 and +23 kcal·mol^{-1} but favored the value of +23 kcal·mol^{-1} in the theoretical calculations of boron burning *in air*.

Heat Capacity and Entropy

The bent molecular structure and the molecular constants were estimated by comparison with those in BO(g), AlO(g) and $Al_2O(g)$. The principal moments of inertia are $I_A = 0.1624 \times 10^{-39}$, $I_B = 5.3179 \times 10^{-39}$, and $I_C = 5.4803 \times 10^{-39}$ $g·cm^2$.

Enthalpy of Formation

$\Delta_f H°(B_2O_2, g, 298.15\ K)$ adopted is the weighted average of three $\Delta_f H°(298.15\ K)$ values derived from two different chemical reactions. The chemical reactions related to the production of $B_2O_2(g)$ have been studied by several investigators. Using the equilibrium vapor pressure data, the respective values of $\Delta_r H°(298.15\ K)$ were evaluated by both the 2nd and 3rd law methods. The results obtained are based on the latter and presented as follows:

Source	Reaction	$\Delta_r H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}
[1]	2/3 B(cr) + 2/3 B_2O_3(l) = B_2O_2(g)	94.0	91.8 ± 2.2	−105.5 ± 0.7*
	2/3 B(cr) + 2/3 B_2O_3(g) = B_2O_2(g)	24.8	25.4 ± 0.2	−108.0 ± 0.5

[3]	2/3 B(cr) + 2/3 B_2O_3(l) = B_2O_2(g)	89.3	77.9 ± 0.2	−110.2 ± 0.9
[4]	B_2O_3(l) + 3 C(cr) = 3 CO(g) + 2 B(cr)	—	—	−108.5 ± 1.5
	B_2O_3(l) + C(cr) = B_2O_2(g) + CO(g)	—	—	

*The value not used for the calculation of the weighted average of $\Delta_f H°(B_2O_2, g, 298.15\ K)$.

Heat Capacity and Entropy

The molecular structure and constants, and vibrational frequencies, corrected to the average isotopic species, were taken from Sommer *et al.*[5]

PREVIOUS: December 1964 (1 atm) CURRENT: December 1964 (1 bar)

$S°(298.15\ K) = 53.95 \pm 0.4\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 723 \pm 0.5\ K$

$\Delta_f H°(0\ K) = -1265.8 \pm 2.1\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1271.9 \pm 2.1\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 24.071 \pm 0.4\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The adopted $\Delta_f H°(B_2O_3, cr, 298.15\ K) = 304.0 \pm 0.5\ kcal \cdot mol^{-1}$ is calculated from JANAF $\Delta_f H°(BF_3, g, 298.15\ K) = -271.42 \pm 0.4\ kcal \cdot mol^{-1}$ [1] and $\Delta_c H°(298.15\ K) = -238.82 \pm 0.39\ kcal \cdot mol^{-1}$ for $B_2O_c(cr) + 3\ F_2(g) \rightarrow 2\ BF_3(g) + 1.5\ O_2(g)$. The enthalpy of combustion of B_2O_3(cr) in fluorine was determined by Johnson and Hubbard.[2] The direct combusion of boron in oxygen has led to $\Delta_f H°$(glass, 298.15 K) values which range from −280 to −368 $kcal \cdot mol^{-1}$ [3-9] due to incomplete combustions or ill-defined states of combustion products. These values are not reliable.

A reliable enthalpy of formation of boric oxide can be derived from enthalpies of solution of H_3BO_3(cr) and B_2O_3(cr) which are listed below. Since the enthalpies of dilution of aqueous H_3BO_3[10] are relatively small, no correction has been applied to the reported enthalpy of solution data. The derived $\Delta_f H°$ values are in very good agreement with the values adopted.

Source	Enthalpy of Solution, $kcal \cdot mol^{-1}$ $\Delta_{sol} H°(B_2O_3, cr)$[a]	$\Delta_{sol} H°(H_3BO_3, cr)$[b]	$\Delta_f H°(cr)$[c] $kcal \cdot mol^{-1}$	$\Delta_f H°(B_2O_3, cr, 298.15\ K)$[d] $kcal \cdot mol^{-1}$
[11]	−3.56*	+5.3	−14.16	−303.83
[12]	−3.41*	+5.10	−13.61	−304.38

[14]	−3.48	+5.27	−14.02	−303.97
[15]	−3.49	+5.17	−13.83	−304.16
[16]	−3.45	+5.45	−14.35	−303.64

*The enthalpy of solution of B_2O_3(am) was combined with $\Delta_f H°(25°C) = 4.44\ kcal \cdot mol^{-1}$ [2] to obtain the $\Delta_{sol} H°(B_2O_3, cr)$
[a] $B_2O_3(cr) + 3\ H_2O(l) \rightarrow 2\ H_3BO_3(aq)$ [b] $H_3BO_3(cr) \rightarrow H_3BO_3(aq)$ [c] $B_2O_3(cr) + 3\ H_2O(l) \rightarrow 2\ H_3BO_3(cr)$
[d] the auxiliary data $\Delta_f H°(H_3BO_3, cr, 298.15\ K)$[1] $= -261.47 \pm 0.2\ kcal/mol^{-1}$ and $\Delta_f H°(H_2O, l, 298.15\ K)$[10] $= -68.315\ kcal\ mol^{-1}$ are used in the calculation.

Other solution calorimetric measurements[17-19] which involve the hydrolysis of B_2H_6(g) and BCl_3(l) lead to enthalpies of formation of boric oxide (cr) with a relatively large uncertainty since the techniques were indirect, and many questionable auxiliary data were employed in the derivation.

Heat Capacity and Entropy

The adopted heat capacities are derived from C_p data of Kerr, Hersh and Johnston[20] and Shmidt[21] in the temperature regions 18–296.6 K and 303–703 K, respectively. These two sets of C_p data were measured adiabatically and are smoothly joined at 298.15 K by a polynomial curve fitting technique. The derived entropy, $S°(298.15\ K)$, is based on $S°(18.08\ K) = 0.025\ cal \cdot K^{-1} \cdot mol^{-1}$.

Kelley[22] also measured low temperature C_p from 53 to 295 K which are in very good agreement with the values adopted. Southard[23] determined high temperature enthalpy data from 350 to 721.5 K by drop calorimetry. The deviations of the observed enthalpy data from the adopted values are about 5% at 360 K, 1% at 570 K and 0.5% at 720 K.

Fusion Data

The melting point, 723 ± 0.5 K, was determined by Schmidt[21] in excellent agreement with the value 723 ± 2 K reported by Kracek *et al.*[24] The adopted enthalpy of fusion, $\Delta_{fus} H° = 5.75 \pm 0.1\ kcal \cdot mol^{-1}$, is derived from $\Delta_f H°(298.15\ K) = 4.44\ kcal \cdot mol^{-1}$ for B_2O_3(crystal) → B_2O_3(am)[2] and the adopted relative enthalpies of the two forms at 723 K. This value is reasonable agreement with $\Delta_{fus} H°(723\ K) = 5.87 \pm 0.1\ kcal \cdot mol^{-1}$ determined calorimetrically by Schmidt.[21]

$S°(298.15\ K) = [78.443 \pm 0.4]\ J \cdot K^{-1} \cdot mol^{-1}$

$T_{fus} = 723 \pm 0.5\ K$

$\Delta_f H°(298.15\ K) = [-1253.359 \pm 2.5]\ kJ \cdot mol^{-1}$

$\Delta_{fus} H° = 24.071 \pm 0.4\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$(l, 298.15 K), is calculated from $\Delta_f H°(25°C) = 4.44 \pm 0.06$ kcal·mol^{-1}[1] for B_2O_3(cr) → B_2O_3(glass), using the JANAF value $\Delta_f H°(B_2O_3, cr, 298.15\ K) = -304.0 \pm 0.5$ kcal·mol^{-1}. The value of $\Delta_t H°$ is the difference between the enthalpies of crystalline and glassy B_2O_3 determined by Johnson and Hubbard.[1]

Heat Capacity and Entropy

Heat capacities of B_2O_3(glass) have been measured adiabatically in the temperature regions 59.6–295 K by Turdakin and Tarasov,[2] and 306.7–910.8 K by Schmidt.[3] Thomas and Parks[4] also measured isothermally the heat capacities from 308 to 594 K in a radiation calorimeter. Both Schmidt[3] and Thomas and Parks[4] observed a rapid rise in heat capacity in the region 500–580 K. This rise indicates a glass transition in liquid B_2O_3.

Southard[5] and Krasovitskaya *et al.*[6] determined enthalpy changes by drop calorimetry in the temperature regions 381.7–1776.8 K and 1015–2154 K, respectively.

We have adopted the C_p data of Turdakin (60–295 K) and Shmidt (307–600 K) which are smoothly joined at 298.15 K by a polynomial curve fitting technique. The drop calorimetric data of Southard in this region 381 to 600 K are less reliable since the final state of the sample was dependent upon previous thermal history through the glass transition region. Above the melting point, we have chosen a constant C_p, 31.0 cal·K^{-1}·mol^{-1}, which is a compromise between the adiabatic C_p and drop calorimetric data. The uncertainty of this choice, ±0.6 cal·K^{-1}·mol^{-1}, is within the experimental errors of both techniques.

$S°(298.15\ K)$ is calculated from that of the crystal by adding $\Delta_{fus} H°/T_{fus}$ and the difference in entropy, $S°(723\ K) - S°(298.15\ K)$, between the crystal and liquid.

Fusion Data

Refer to the crystal table for details.

Vaporization Data

The boiling point is calculated as the temperature at which the fugacity is 1 bar for $B_2O_3(l) \rightarrow B_2O_3(g)$. The enthalpy of vaporization is the difference in $\Delta_f H°$ at the boiling point between liquid and gas.

Enthalpy of Formation

The vapor pressure of B_2O_3(l) was measured by many investigators using various methods. 2nd and 3rd law analyses of these data[1-11] are given below. We have adopted the 3rd law enthalpy of vaporization, $\Delta_{vap}H°(298.15\ K) = 99.75$ kcal·mol^{-1}, to derive $\Delta_f H°(B_2O_3, g, 298.15\ K) = -199.8 \pm 1$ kcal·mol^{-1}, using $\Delta_f H°(B_2O_3, l, 298.15\ K) = -299.56$ kcal·mol^{-1}. The adopted $\Delta_{vap}H°(298.15\ K)$ is calculated from Hildenbrand's data[1] and this value also serves as an average of all derived enthalpies of vaporization except that of Cole.[11] The uncertainty is assigned to be at least ±1 kcal·mol^{-1} since the bending frequency was estimated to be either 172 or 260 cm^{-1} [12] which could lead to a difference ±1 kcal·mol^{-1} in the $\Delta_{vap}H°$ calculation through the Gibbs energy functions of B_2O_3(g).

[a] Four points were rejected due to failure of a statistical test.

Heat Capacity and Entropy

The V shaped molecular structure for B_2O_3 was proposed by many investigators on the basis of infrared spectrometry[12, 13] and electron diffraction.[14] This structure has been reconfirmed by recent electric deflection[15] and electron diffraction[16] studies which definitely rule out any non polar structure such as the bipyramidal model as suggested by Hanst *et al.*[17] Thus the assignment of vibrational frequencies, based on the V shaped structure, should be valid. The adopted vibrational frequencies (including two estimated values) were obtained from Sommer *et al.*[12] in their infrared spectrometric studies. Their values have been adjusted to the average isotopic species. Other spectrometric data[13, 18] are in reasonable agreement with those adopted in the tabulation.

Akishin and Spiridonov[14] determined the bond distances and bond angle (B–O–B = 95°) by electron diffraction. We have adopted their bond distances in the tabulation, but tentatively select an apex angle B–O–B = 120° based on force constant calculations of Weltner and Warn[13] and Sommer *et al.*[12] The principal moments of inertia are $I_A = 2.9763 \times 10^{-39}$, $I_B = 31.0977 \times 10^{-39}$ and $I_C = 34.0740 \times 10^{-39}$ g·cm^2.

$S°(298.15\ K) = [130.5 \pm 12]\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K)$ = Unknown

$\Delta_f H°(298.15\ K) = -1556 \pm 6\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Evans[1] analyzed the enthalpies of formation of the lead borate system. Shartsis and Newman measured enthalpies of solution of the lead borate glasses in 2 N HNO_3. In their phase studies, Mazzetti and De Carli[3] established that the compounds formed were $PbO \cdot B_2O_3$, $PbO \cdot 2B_2O_3$ and $2PbO \cdot 5B_2O_3$. From the Shartsis and Newman[2] paper, Evans[1] obtained the following:

$$PbO(cr) + B_2O_3(cr) \rightarrow PbOB_2O_3(gls) \qquad \Delta_r H° = -16.2\ kcal \cdot mol^{-1}$$

and estimated a $\Delta_f H°(298.15\ K)$ of 7.0 $kcal \cdot mol^{-1}$ for the conversion to the $PbOB_2O_3$(cr). With auxiliary JANAF values, the $\Delta_f H°(298.15\ K)$ was calculated to be −372 $kcal \cdot mol^{-1}$. The results of Lepinskikh and Esin[4] studying the lead borate system at 1000 K with cells of the type $Pb(l)/PbO,B_2O_3/Pt/O_2(g)$ were in fair agreement with the results of Shartsis and Newman.[2]

Heat Capacity and Entropy

The heat capacity employed in this table was obtained by graphically smoothing the summation of the heat capacities for $B_2O_3$and PbO.

The entropy at 298.15 was obtained from a consideration of the entropies of sodium and calcium borates and those of the constituent oxides, as given by Kelley and King.[5] These indicate for the reaction $MO + B_2O_3 \rightarrow MoB_2O_3$ that the simple addition of entropies will give values at least 2.7 $cal \cdot K^{-1} \cdot mol^{-1}$ too low for the reaction. The reason for this is probably structural, the $B_2O_4^{--}$ ion is a flexible chain. Therefore, $S°(PbB_2O_4$, cr, 298.15 K) was obtained from the summation of $S°(298.15\ K)$ for constituent oxides and the addition of 2.7 $cal \cdot K^{-1} \cdot mol^{-1}$.

$S°(298.15\ K) = 28.48 \pm 0.4\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 3193\ K$

$\Delta_f H°(0\ K) = -277.8 \pm 16.7\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -279.5 \pm 16.7\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = [100.4]\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Kibler *et al.*[1] studied the vapor pressure of the reaction $TiB_2(cr) + 1/2\ C(cr) = Ti(g) + 1/2\ B_4C(cr)$ by comparing the absorption intensity of the 3371.45 Å Ti resonance line of the above reaction at temperature T_1 to Ti(g) over pure titanium metal at temperature T_2. Using JANAF auxiliary data, $\Delta G°(2475\ K) = 81.612\ kcal \cdot mol^{-1}$ for the above reaction and $\Delta_f H°(TiB_2, cr, 298.15\ K) = -66.9\ kcal \cdot mol^{-1}$ were calculated.

Williams[2] found 2150 ± 25 K to be the temperature at which $TiB_2(cr)$ was formed from a mixture of TiN(cr) and BN(cr). If $\Delta G°(2150\ K) = 0$ is assumed for the reaction $TiN(cr) + 2\ BN(cr) = TiB_2(cr) + 3/2\ N_2(g)$, then $\Delta_f H°(TiB_2, cr, 298.15\ K) = -70.7\ kcal \cdot mol^{-1}$. If, however, $N_2(g)$ is 1/2 atm, then $\Delta G°(2150\ K) = 4.4\ kcal \cdot mol^{-1}$ and $\Delta_f H°(TiB_2, cr, 298.15\ K) = -66.3\ kcal \cdot mol^{-1}$. He has also shown by stability comparisons that ΔG and $\Delta H > 0$ for the reaction $TiB_2 + 3/2\ C = TiC + 1/2\ B_4C$. Thus $\Delta_f H°(TiB_2, 298.15\ K) < -51\ kcal \cdot mol^{-1}$.

Schissel and Trulson[3] used a mass spectrometer with Knudsen cells to study the vaporization of the titanium–boron system. Only the set of measurements without excess boron or titanium was used. The value $\Delta G°(2261\ K) = 194.9\ kcal \cdot mol^{-1}$ for the reaction $TiB_2(cr) = Ti(g) + 2\ B(g)$ was obtained. This corresponds to $\Delta_f H°(TiB_2, cr, 298.15\ K) = -62.9\ kcal \cdot mol^{-1}$ using JANAF auxiliary data.

Epel'baum and M. I. Starostina[4] report $\Delta_f H°(TiB_2, cr, 298.15\ K) = -66.85 \pm 2.7\ kcal \cdot mol^{-1}$ from combustion calorimetry.

Lowell and Williams[5] used high temperature calorimetry to obtain the enthalpy of formation of $TiB_2(cr)$. From their data and JANAF auxiliary data, $\Delta_f H°(TiB_2, cr, 298.15\ K) = -48.2 \pm 5\ kcal \cdot mol^{-1}$ was calculated. We question the authenticity of the experiment and believe their value is an upper limit.

$\Delta_f H°(TiB_2, cr, 298.15\ K) = -66.8 \pm 4\ kcal \cdot mol^{-1}$ was chosen as representative of the first four investigations.

Heat Capacity and Entropy

The heat capacity of $TiB_2(cr)$ has been determined by the following investigators.

Source	Method	T/K
[6]	Adiabatic Calorimetry	5–350
[7]	Drop calorimeter	373–977
[8]	Drop type ice calorimeter	586–2689
[9]	Copper–block drop calorimeter	420–1180
[10]	Arc–imaging furnace	1300–2150
[11]	Pulse–method	1733–2417

The low temperature data of Westrum[1] and the medium range data of Walker *et al.*[7] were used to obtain the C_p's of this tabulation. Their data were fitted to a Shomate plot and extrapolated to 4000 K.

$S°(298.15\ K) = 6.808\ cal \cdot K^{-1} \cdot mol^{-1}$ was determined by Westrum.[1]

Fusion Data

The melting point has been reported as 3063 K, 3193 K, and 3203 K by Glaser,[12] Post *et al.*,[13] and Samsonov and Petrash,[14] respectively. The enthalpy of fusion is derived from an estimated $\Delta_{fus} S = 2.5\ cal \cdot K^{-1}\ g\ atom^{-1}$ at 3193 K. It should be pointed out that an error of 0.5 $cal \cdot K^{-1} \cdot mol^{-1}\ g\ atom^{-1}$ in the estimation of $\Delta_{fus} S°$ is 5 $kcal \cdot mol^{-1}$ in $\Delta_{fus} H°$.

$S°(298.15\ K)$ = [56.365] $J·K^{-1}·mol^{-1}$
T_{fus} = 3193 K
T_{dcm} = [4250] K

$\Delta_f H°(298.15\ K)$ = [−188.029] $kJ·mol^{-1}$
$\Delta_{fus}H°$ = [100.4] $kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(TiB_2, l, 298.15\ K)$ is calculated from $\Delta_f H°(TiB_2, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus}H°$, and the difference in enthalpy, $H°(3193\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

A glass transition is assumed at 2100 K. Heat capacities at and below 2100 K are assumed to be equal to those of TiB_2(cr). Above 2100 K the heat capacities are estimated to be constant.

$S°(TiB_2, l, 298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

Refer to the crystal table for details.

Decomposition Data

T_{dcm} is estimated as the temperature for which $\Delta_r G° = 0$ for the reaction $TiB_2(l) \rightarrow Ti(g) + 2\ B(g)$.

Enthalpy Reference Temperature = T_r = 298.15 K **Standard State Pressure = $p°$ = 0.1 MPa**

PREVIOUS: CURRENT: June 1965

$S°(298.15\ K) = 35.94 \pm 0.04\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 3323\ K$

$\Delta_f H°(0\ K) = -321.3 \pm 6.7\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -322.6 \pm 6.7\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = [104.6]\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Johnson[1] reported $\Delta_f H°(ZrB_{1.999 \pm 0.006}, cr, 298.15\ K) = -78.7 \pm 1.5\ kcal \cdot mol^{-1}$. Their value was obtained by fluorine bomb calorimetry and was based on their recently redetermined value of $\Delta_f H°(BF_3, g, 298.15\ K) = -271.80 \pm 0.20\ kcal \cdot mol^{-1}$.

Kibler *et al.*[2] studied the vaporization of $ZrB_{1.931}$ by the Knudsen effusion method. Over the range 2260 to 2500 K, $\log K_p = 22.038 - 0.164 \times 10^4/T$ for the reaction $ZrB_{1.931}(cr) = Zr(g) + 1.931\ B(g)$. JANAF auxiliary data were used to calcuate $\Delta_r H°(298.15\ K) = 478.5 \pm 1.5\ kcal \cdot mol^{-1}$ by the 3rd law method and $\Delta_f H°(ZrB_{1.932}, cr, 298.15\ K) = -76.7 \pm 3.2\ kcal \cdot mol^{-1}$.

Trulson and Goldstein[3] investigated the decomposition vapor pressure of the reaction $ZrB_2(cr) = Zr(g) + 2\ B(g)$ and reported $\Delta_f H°(ZrB_2, cr, 298.15\ K) = -72.1 \pm 5.3\ kcal \cdot mol^{-1}$. They also reported $\Delta_r H°(298.15\ K) = 289.7\ kcal \cdot mol^{-1}$ for the reaction $ZrB_2(cr) + C(cr) = ZrC(cr) + 2\ B(g)$. Using the JANAF $\Delta_f H°(ZrC, cr, 298.15\ K) = -47.0 \pm 3\ kcal \cdot mol^{-1}$, $\Delta_f H°(ZrB_2, cr, 298.15\ K) = -76.1 \pm 3\ kcal \cdot mol^{-1}$ was calculated. JANAF values for $\Delta_{vap} H°(B, g, 298.15\ K)$ and Zr(g) were not used since their independent determinations serve to cancel instrumental constants.

From oxygen bomb calorimetry, Huber *et al.*[4] reported $\Delta_f H°(ZrB_2, cr, 298.15\ K) = -77.2 \pm 1.2\ kcal \cdot mol^{-1}$.

$\Delta_f H°(ZrB_2, cr, 298.15\ K) = -77.1 \pm 1.6\ kcal \cdot mol^{-1}$ was chosen as a value representative of the above.

Heat Capacity and Entropy

The heat capacity of ZrB_2(cr) has been determined by the following investigators.

	Source	Method	T/K
5		Adiabatic calorimetry	5–350
6		Copper–block drop calorimeter	410–1125
7		Copper–block drop calorimeter	430–1170
8		Arc–imaging furnace	1300–2150
9		Pulse–method	1740–2520
10		Drop type ice calorimeter	500–2500

Westrum and Feick's[5] values were adopted to 350 K. The disparities in heat capacities above room temperatures seem too great to be errors in measurement and are probably due to sample differences. Since the samples used by Westrum and Feick[5] and by Valentine *et al.*[6] were from the same batch, Valentine's data were used above 350 K. The two sets of data were fitted to a Shomate plot which was extrapolated to 4000 K. However, in consideration of the results of Mezsaki,[7] Prophet[8] and Neel *et al.*,[10] the C_p extrapolation ran somewhat higher than a direct extrapolation of Valentine's data would yield.

$S°(ZrB_2, 298.15\ K) = 8.59\ cal \cdot K^{-1} \cdot mol^{-1}$ was determined by Westrum.[5]

Fusion Data

The melting point has been reported as 3313, 3323 and 3265 K by Glaser and Post,[11] Post *et al.*[12] and Greenwood,[13] respectively. The enthalpy of fusion is derived from an estimated $\Delta_{fus} S° = 2.5\ cal \cdot K^{-1}$ g-atom^{-1} at 3323 K. It should be pointed out that an error of 0.5 $cal \cdot K^{-1}$ g-atom^{-1} in the estimation of $\Delta_{fus} S°$ is 5 $kcal \cdot mol^{-1}$ in $\Delta_{fus} H°$.

PREVIOUS: March 1963 CURRENT: June 1965

$S°(298.15\ K) = [64.742]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 3323\ K$
$T_{dcm} = [4466]\ K$

$\Delta_f H°(298.15\ K) = [-224.832]\ kJ·mol^{-1}$
$\Delta_{fus} H° = [104.6]\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(ZrB_2, l, 298.15\ K)$ is calculated from $\Delta_f H°(ZrB_2, cr, 298.15\ K)$ by adding the enthalpy of fusion, $\Delta_{fus} H°$, and the difference in enthalpy, $H°(3323\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

A glass transition is assumed at 2200 K. The heat capacities at and below 2200 K are assumed to be equal to those of ZrB_2(cr). Above 2200 K the heat capacities were estimated to be constant.

$S°(ZrB_2, l, 298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

Refer to the crystal table for details.

Decomposition Data

T_{dcm} is estimated as the temperature for which $\Delta_r G° = 0$ for the reaction $ZrB_2(l) = Zr(g) + 2\ B(g)$.

Enthalpy Reference Temperature = T_r = 298.15 K Standard State Pressure = $p°$ = 0.1 MPa

Ground State Quantum Weight: [1] $\sigma = 6$

Point Group: [D_{3h}]

Bond Distances: B–Cl = [1.75] Å; B–O = [1.36] Å

Bond Angles: Cl–B–O = [120]°; B–O–B = [120]°

Product of the Moments of Inertia: $I_A I_B I_C$ = [1.868800 × 10^{-111}] $g^3·cm^6$

Enthalpy of Formation

The equilibrium constants for the reaction $B_2O_3(l) + BCl_3(g) = (BOCl)_3(g)$ were determined by Blauer and Farber in the temperature range 536–825 K by a transpiration method,[1] and in the temperature range 1234–1309 K by an effusion method.[2] Using the reported equilibrium constants, the enthalpy changes for this reaction were evaluated by both the 2nd and 3rd law methods.

Method Used	$\Delta_f H°(298.15\ K)$, $kcal·mol^{-1}$ 3rd law	2nd law	$\Delta_f H°(293.15\ K)$ $kcal·mol^{-1}$
Transpiration	5.31	5.07 ± 0.4	−390 ± 2
Effusion	12.57	5.85 ± 3.3	−386 ± 3

By a mass spectroscopic method the enthalpy change $\Delta_f H°(1000\ F) = 16.6 \pm 2.5$ kcal mol^{-1}, for the reaction $BCl_3(g) + B_2O_3(l) = (BOCl)_3(g)$ was determined by Porter and Gupta.[3] The $\Delta_f H°(298.15\ K)$ value for $(BOCl)_3(g)$ was derived as -377 ± 3 $kcal·mol^{-1}$. However, it is possible that the intensity of $B_3O_3Cl_3^+$, employed to plot the ion ratios $I(B_3O_3Cl_3^+)/I(BCl_2^+)$ versus $1/T$, does not fully reflect the concentration of $B_3O_3Cl_3$ especially at the highest temperatures, due to changes in the fragmentation pattern with temperature.

The value of $\Delta_f H°(298.15\ K)$ adopted for $(BOCl)_3(g)$ is 390 ± 2 $kcal·mol^{-1}$ derived from transpiration data. The effusion data were measured in the temperature range where Porter and Gupta[3] found the presence of $(BOCl)_4(g)$. However, this point was not taken into consideration in the report. Hence, the corresponding $\Delta_f H°(298.15\ K)$ value was not adopted.

Heat Capacity and Entropy

The vibration frequencies are estimated by comparison with related molecules such as $B_3O_3F_3(g)$ and $(BH_2O)_3(g)$. The B–Cl bond distance is assumed to be the same as that in $BCl_3(g)$. The B–O bond distance and all bond angles are estimated. The principal moments of inertia are: $I_A = I_B = 97.7637 \times 10^{-39}$, and $I_C = 195.5274 \times 10^{-39}$ $g·cm^2$.

Ground State Quantum Weight: [1] $\sigma = 2$
Point Group: [C_{2v}]
Bond Distances: B–O = [1.36] Å; B–H = [1.18] Å; B–F = [1.41] Å
Bond Angles: B–O–B = [120]°; O–B–H = [120]°; O–B–F = [120]°
Product of the Moments of Inertia: $I_A I_B I_C$ = [2.164977 × 10^{-113}] $g^3·cm^6$

Enthalpy of Formation

The equilibrium constants (K), 1246–1326 K, for the two reactions $2B_3O_3F_2H(g) = B_3O_3FH_2(g) + B_3O_3F_3(g)$ and $2B_3O_3FH_2(g) = B_3O_3H_3(g) + B_3O_3F_2H(g)$ were reported by Porter and Sholette.[1] The $\Delta_f H°(298.15\ K)$ for $B_3O_3H_2F(g)$ adopted was evaluated by use of K values slightly outside the ranges given by Porter and Sholette. See the table for $B_3O_3F_2H(g)$ for details.

Heat Capacity and Entropy

The structure is assumed to be a planar six membered ring structure of C_{2v} symmetry, which has 21 vibrations of the type $8A_1$, $7B_1$, $2A_2$, and $4B_2$. These frequencies are estimated from the values for boroxin and trifluoroboroxin, the symmetry being reduced from D_{3h} as follows: $3A'_1 \rightarrow 3A_1$, $2A'_2 \rightarrow 2B_1$, $5E' \rightarrow 5A_1 + 5B_1$, $2A_2 \rightarrow 2B_2$ and $2E'' \rightarrow 2A_2 + 2B_2$.

The B–F distance is taken as approximately equal to that in $(CH_3)_2O\ BF_3$ reported by Bauer, Findlay and Laubengayer.[2] The other bond lengths and angles are taken equal to those in boroxin. The principal moments of inertia are: $I_A = 13.9711 \times 10^{-39}$, $I_B = 32.9946 \times 10^{-39}$, and $I_C = 46.9657 \times 10^{-39}$ $g·cm^2$.

Enthalpy of Formation

The stabilities of gaseous boroxin ($B_3O_3H_3$) and its fluoro derivatives have been studied by Porter and Sholette.[1] From the mass spectra of the gaseous reaction products generated by reaction of an H_2–BF_3 mixture on B_2O_3 at 1250 K, the equilibrium constants (K) for the following proposed reactions were reported.

Reaction	T/K	K	$\Delta_f H°$(298.15 K), $kcal·mol^{-1}$
(1) $H_2(g) + B_3O_3F_3(g) = HF(g) + B_3O_3F_2H(g)$	1246–1326	4.2×10^{-3}–2.3×10^{-2}	20.45–17.17
(2) $2B_3O_3F_2H(g) = B_3O_3FH_2(g) + B_3O_3F_3(g)$	1246–1326	0.62–0.46	1.28–2.15
(3) $2B_3O_3FH_2(g) = B_3O_3H_3(g) + B_3O_3F_2H(g)$	1246–1326	1.0–0.63	−2.56–−1.51

Using these reported K values the corresponding enthalpy changes are evaluated by the 3rd law method. The results obtained are listed in the above table. Based on $\Delta_f H°(298.15\ K) = -565.3$ and $-64.8\ kcal·mol^{-1}$ for $B_3O_3F_3(g)$ and HF(g), respectively, the value of $\Delta_f H°(298.15\ K)$ for $B_3O_3F_2H(g)$ is calculated from Reaction (1) as $-482\ kcal·mol^{-1}$. From Reaction (2), the $\Delta_f H°(298.15\ K)$ value for $B_3O_3FH_2(g)$ is calculated as $-397\ kcal·mol^{-1}$. However, employing $\Delta_f H°(B_3O_3H_3, g, 298.15\ K) = -291\ kcal·mol^{-1}$, the values of $\Delta_f H°(298.15\ K)$ for $B_3O_3FH_2(g)$ and $B_3O_3F_2H(g)$ thus obtained do not fit properly for Reaction (3). Therefore, the $\Delta_f H°(298.15\ K)$ for $B_3O_3FH_2(g)$ and $B_3O_3F_2H(g)$ adopted are evaluated by use of K values slightly outside the ranges given by Porter and Sholette.[1]

Heat Capacity and Entropy

The vibrational frequencies are obtained by comparison with $B_3O_3F_3(g)$ and $B_3H_3O_3(g)$. The types of vibration and symmetry are identical to those given for $B_3O_3H_2F(g)$. The bond angles and lengths are taken equal to those for $B_3O_3H_2F(g)$. The principal moments of inertia are: $I_A = 22.0494 \times 10^{-39}$, $I_B = 48.6611 \times 10^{-39}$, and $I_C = 70.7105 \times 10^{-39}\ g·cm^2$.

$\Delta_{fus} H°$ = Unknown

Enthalpy of Formation

The enthalpies of solution of the compounds: B_2O_3(gl), BF_3(g) and $(BOF)_3$(cr) in water and methanol, respectively, were reported by Magee.[1] The corresponding enthalpy changes for the reaction B_2O_3(gl) + BF_3(g) = $(BOF)_3$(cr) were derived as −19.8 and −14.4 kcal·mol^{-1}, yielding $\Delta_f H°$(298.15 K) values for $(BOF)_3$(cr) as −589.18 and −583.78 kcal·mol^{-1}, respectively. The adopted value of $\Delta_f H°$(298.15 K) for $(BOF)_3$(cr) is the average of these two values obtained.

Heat Capacity and Entropy

The heat capacities for $(BOF)_3$(cr) are estimated from the C_p values for B_2O_3(cr) and BF_3(g), according to the method suggested by Kubaschewski and Evans.[2]

$S°$(298.15 K) for $(BOF)_3$(cr) was estimated by Magee.[1]

Fusion Data

The value of T_{fus} was reported by Magee.[1]

Sublimation Data

The enthalpy of sublimation for $(BOF)_3$(cr) is calculated as the difference in $\Delta_f H°$(298.15 K) between the crystal and gas.

Ground State Quantum Weight: [1] $\sigma = 6$
Point Group: $[D_{3h}]$
Bond Distances: B–F = [1.3] Å; B–O = [1.36] Å
Bond Angles: F–B–O = [120]°; B–O–B = [120]°; O–B–O = [120]°
Product of the Moments of Inertia: $I_A I_B I_C = [1.925790 \times 10^{-113}]\ g^3·cm^6$

Enthalpy of Formation

The enthalpy changes of the reaction $B_2O_3(l) + BF_3(g) = (BOF)_3(g)$ are derived by both the 2nd and 3rd law methods, using the equilibrium constant data reported by several investigators.

Source	$\Delta_r H°$(298.15 K), kcal·mol^{-1} 3rd law	2nd law	$\Delta_f H°$(298.15 K) kcal mol^{-1}
Hildenbrand, *et al.*[1]	4.06	4.01 ± 0.3	−565.32 ± 1.0
Fisher, *et al.*[2]	3.41	6.45 ± 0.6	−565.97 ± 1.5
Smith and Lawrence[3]	4.03	—	−565.35 ± 1.3
Farber[4]	5.25	—	−565.13 ± 2.0
	2.56	7.58 ± 0.2	−565.82 ± 2.0
Porter, *et al.*[5]	—	4.33 ± 0.30	−565.05 ± 1.0

The adopted value of $\Delta_f H°$(298.15 K) for $(BOF)_3$(cr) is the weighted average of the six $\Delta_f H°$(298.15 K) values listed above.

Heat Capacity and Entropy

The infra-red spectrum has been reported by Smith and Lawrence[3] and by Fisher, Lehmann, and Shapiro[6] who also made a partial assignment. The unassigned bands at 1280 and 1233 from Fisher, *et al.*,[6] can be assigned to the A_2^1 and A_1^1 species which may be observed if the selection rules are not rigorously obeyed in the solid. All the unobserved frequencies were estimated by comparison with $B_3O_3(OH)_3$, $B_3O_3(OD)_3$ from Parsons[7] and $B_3O_3H_3$ and $B_3O_3D_3$ from Gupta and Porter[8] and Lee, Bauer and Wiberley.[9] The D_{3h} assumed symmetry has 14 vibrations of the type $3A_1^1$, $2A_2^1$, 5E', $2A_2^{11}$ and 2E" which are given in order above. The B–F bond distance was assumed to be the same as that in BF_3. The B–O bond distance was estimated by comparison with other related compounds. The principal moments of inertia are: $I_A = I_B = 45.8345 \times 10^{-39}$, and $I_C = 91.6691 \times 10^{-39}$ g·cm^2.

$S°(298.15\ K) = [167 \pm 42]\ J \cdot K^{-1} \cdot mol^{-1}$
T_{fus} = Unknown

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -1262.3 \pm 42\ kJ \cdot mol^{-1}$
$\Delta_m H°$ = Unknown

Enthalpy of Formation

The value of $\Delta_f H°(298.15\ K)$ for $B_3O_3H_3$(cr) is calculated from the $\Delta_f H°(298.15\ K)$ for $B_3O_3H_3$(g) and $\Delta_{sub} H°(298.15\ K)$ for $B_3O_3H_3$(cr) reported by Porter and Gupta.[1]

Heat Capacity and Entropy

The heat capacities were estimated from those from B_2O_3(cr) and 1/2 B_2H_6Kubaschewski and Evans.[2] The value of $S°(298.15\ K)$ for $B_3O_3H_3$(cr) is calculated based on $\Delta_r S°(298.15\ K) = 6.6\ cal \cdot K^{-1} \cdot mol^{-1}$ for the reaction $B_3O_3H_3(cr) = B_2O_3(am) + 1/2\ B_2H_6(g)$, which was obtained from the calculated $\Delta_f H°(298.15\ K)$ and measured $\Delta_f G°(298.15\ K)$ evaluated from the vapor pressure reported by Sholette and Porter.[3]

Sublimation Data

$\Delta_{sub} H°(298.15\ K)$ is taken from Porter and Gupta.[3]

Enthalpy of Formation

The equilibrium constants (1290–1481 K) for the reaction (1) 3/2 $H_2(g)$ + B(am) + $B_2O_3(l)$ = $B_3O_3H_3(g)$ were determined by Sholette and Porter.[1] The equilibrium pressures of $B_2H_6(g)$ and $B_3O_3H_3(g)$ for the reaction (2) $B_3O_3H_3(g)$ = 1/2 $B_2H_6(g)$ + $B_2O_3(cr)$ were measured at 300 K by Porter and Gupta.[2] The equilibrium constants (1246–1326 K) for the reaction[3] $2B_3O_3FH_2(g) = B_3O_3H_3(g) + B_3O_3F_2H(g)$ were reported by Porter and Sholette.[3] Using these data the corresponding enthalpy changes were evaluated by both the 2nd and 3rd law methods.

(3)	−2.0	—	−314 ± 12.0

**The initial system for the first set of measurements was $B_2H_6(g)$ + $B(OH)_3(cr)$.
That for the second set was $B_2H_6(g)$ + $B_2O_3(gl)$.

The value of $\Delta_f H°(298.15\ K)$ for $B_3O_3H_3(g)$ adopted is a weighted average of these $\Delta_f H°(298.15\ K)$ values listed.

Heat Capacity and Entropy

The infrared spectrum os solid boroxin has been determined by Gupta and Porter[4] and a partial assignment was made. The infrared spectra of the gas has also been reported by Lee, Bauer, and Wiberley[5] and is in essential agreement with the solid. The assignment of the frequencies has been changed slightly due to the non–appearance of the band at 1115 cm^{-1} in the gas phase. The assumed D_{3h} symmetry has 14 vibrations of the type $3A_1'$, $2A_2'$, 5E', $2A_2''$, and 2E'', and 7 estimated frequencies were obtained by comparison with $B_3O_6H_3$, by Parsons.[6]

The point group, bond angles and bond lengths were assumed to be the same as for $(BOF)_3(g)$. The B–H bond length was taken as the sum of the single covalent radii of the atoms. The principal moments of inertia are: $I_A = I_B$ = 13.9710 × 10^{-39}, and I_C = 27.9421 × 10^{-39} $g·cm^2$.

Enthalpy of Formation

The equilibrium constant, K_f (1451 K) = 0.9 for the reaction $H_3BO_3(l) + B_2O_3(l) = (HBO_2)_3(g)$ was reported by Meschi, Chupka and Berkowitz,[1] which was determined by means of mass spectrometry. The equilibrium constants of the reactions between water vapor and liquid B_2O_3 were determined at 1147 K by Blauer and Farber[2] by use of a transpiration method. From the reported value, $1.5\ K_2 + 0.5\ K_3 = 0.0342 \pm 0.0095$, the equilibrium constant, K_2, for the reaction $1.5\ B_2O_3(l) + 1.5\ H_2O(g) = (HBO_2)_3($ derived as 0.0168, using $K_3 = 0.0181$ for the reaction $0.5\ B_2O_3(l) + 1.5\ H_2O(g) = H_3BO_3(g)$ evaluated by use of JANAF values of $\Delta_f G°$ for $B_2O_3(l)$, $H_2O(g)$ and $H_3BO_3(g)$. Employing the equilibrium constants obtained, the respective enthalpy changes for the two reactions were calculated by the 3rd law method. The corresponding values of $\Delta_f H°(298.15\ K)$ for $(HBO_2)_3(g)$ were also derived.

Source	Chemical Reaction	$\Delta_f H°(298.15\ K)$ $kcal·mol^{-1}$	$\Delta_f H°(298.15$ $kcal·mol^{-1}$
Meschi, *et al.*[1]	$H_3BO_3(l) + B_2O_3(l) = (HBO_2)_3(g)$	−7.31	−543.8
Blauer and Farber[2]	$1.5\ B_2O_3(l) + 1.5\ H_2O(g) = (HBO_2)_3(g)$	−6.67	−542.3

The adopted value of $\Delta_f H°(298.15\ K)$ for $(HBO_2)_3(g)$ is the average of these two listed in the above table. The equilibrium constants for the same reactions between $B_2O_3(l)$ and $H_2O(g)$ were also determined by a transpiration method in the temperature region 1000–1273 K by Randall and Margrave.[3] The reported value, $\Delta_f H°(0\ K) = -537.5 \pm 3$ $kcal·mol^{-1}$ for $(HBO_2)_3(g)$, is in good agreement with the value adopted.

Heat Capacity and Entropy

All the molecular and spectroscopic constants were estimated by White, Mann, Walsh, and Sommer.[4] The principal moments of inertia are: $I_A = 43.6915 \times 10^{-39}$, $I_B = 45.5585 \times 10^{-39}$, and $I_C = 89.2499 \times 10^{-39}$ $g·cm^2$. The infrared absorption spectra for $B_3O_3(OH)_3$(cr) in the 430 to 4000 cm^{-1} was reported by Parsons.[5] A partial Raman spectrum was also given.

Ground State Quantum Weight: 1 $\sigma = 6$
Point Group: D_{3h}
Bond Distances: B–N = 1.44 Å; B–H = 1.20 Å; H–N = 1.02 Å
Bond Angles: N–B–N = 120°; B–N–B = 120°; N–B–H = 120°
Product of the Moments of Inertia: $I_A I_B I_C = 8.326395 \times 10^{-114}\ g^3·cm^6$

Enthalpy of Formation

The enthalpy of combustion for the reaction $B_3N_3H_6(l) + 15/4\ O_2(g) + 3/2\ H_2O(l) = 3\ H_3BO_3(c) + 3/2\ N_2(g)$ was reported to be -552.9 ± 3.0 kcal·mol^{-1} by Kilday, Johnson and Prosen.[1] $\Delta_f H°(H_3BO_3, cr, 298.15\ K) = -261.47$ kcal·mol^{-1} from JANAF tables were used to calculate $\Delta_f H°(B_3N_3H_6, l, 298.15\ K) = -129.0 \pm 3.0$ kcal·mol^{-1}. Vapor pressure data on $B_3N_3H_6(l)$ reported by Stock and Pohland[3] were fitted to a linear least squares. ΔC_p(l–g) for borazine was approximated by benzene to calculate a 2nd law $\Delta_{vap} H°(298.15\ K) = 7.1 \pm 0.1$ kcal·mol^{-1}.

Heat Capacity and Entropy

The fundamental frequency assignment was made by Crawford and Edsall.[4] The three frequencies enclosed by brackets are calculated values. The principal moments of inertia are calculated from molecular constants given by Bauer.[5] The principal moments of inertia are: $I_A = I_B = 16.0870 \times 10^{-39}$, and $I_C = 32.1740 \times 10^{-39}\ g·cm^2$.

PREVIOUS: March 1965 (1 atm) CURRENT: March 1965 (1 bar)

$S°(298.15\ K) = [208.4 \pm 6.3]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 1088\ K$

$\Delta_f H°(0\ K) = Unknown$
$\Delta_f H°(298.15\ K) = -3334.2\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 104.5 \pm 4.2\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ was recalculated from the experimental data of Shartsis and Capps.[1] They studied the enthalpy of solution of various alkali borates in 2N nitric acid. Average molecular weights were used for physical mixtures of the oxides B_2O_3 and R_2O (where R is either Li, Na, or K) rather than for the borate compounds $R_2O \cdot nB_2O_3$ present. These incorrect molecular weights led to spurious correlations and faulty conclusions. In reinterpreting the data, the steps followed were: (1) The calculation of the correct molecular weights and molar enthalpies of reaction; (2) The establishment that the enthalpy of formation of the borates from the oxides is linear with the mole fraction of B_2O_3 in the total original moles of oxides for the reactions

$$R_2O(cr) + nB_2O_3(gl) \rightarrow R_2O \cdot nB_2O_3(gls) \quad (I)$$
$$\text{and } R_2O(cr) + nB_2O_3(gl) \rightarrow R_2O \cdot nB_2O_3(cr) \quad (II)$$

With the enthalpy of formation being zero at 100 percent R_2O; (3) The evaluation of the least square fit of the line through the enthalpy of reaction data for reaction I and for reaction II: (4) The use of the proper weighting factors in applying least squares to adjust for both the sample size and the molecular weight of the mixture of borates used in each solution experiment.

Heat Capacity and Entropy

The enthalpy measurements of Smith,[2] in the range 298–973 K were smoothed graphically and were used to obtain a smooth set of C_p data. The heat capacity was extrapolated smoothly above this region. The entropy at 298.15 K is estimated from that of $Na_2B_4O_7$(cr) by using an average entropy change of $4.5 \pm 1.5\ cal \cdot K^{-1} \cdot mol^{-1}$ on substituting Na_2 by K_2.

Fusion Data

T_{fus} was given by Rollet.[3] The enthalpy of melting was obtained from the enthalpies of formation of the crystal and glass at 298.15 K combined with the enthalpy differences between 298.15 K and 1088 K. This involves a slight extrapolation of the crystal data and an uncertainty of about $1.0\ kcal \cdot mol^{-1}$.

$S°(298.15\ K) = [237.120]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1088\ K$

$\Delta_f H°(298.15\ K) = [-3289.042]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 104.5 \pm 4.2\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of formation is obtained form reaction (1), as given on the crystal table.

Heat Capacity and Entropy

The enthalpy measurements of Smith[1] in the range 298 to 1373 K on the glass and liquid were smoothed graphically and used to determine C_p. There is a discontinuity (glass transition) in the C_p curve at 676 K. Above 1373 K the C_p values were extrapolated smoothly.

The entropy at 298.15 K is calculated from that of the crystal by adding $\Delta_{fus}S°$ and the entropy differences, $S°(1088\ K)–S°(298.15\ K)$, between the crystal and liquid.

Fusion Data

Refer to the crystal table for details.

PREVIOUS: CURRENT: March 1963

$S°(298.15\ K) = [155.6 \pm 4.2]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 1190 \pm 2\ K$

$\Delta_f H°(0\ K) =$ Unknown
$\Delta_f H°(298.15\ K) = -3362.3 \pm 6.3\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° \approx 120.5 \pm 6.3\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The enthalpy of formation was calculated from $\Delta_r H°(298.15\ K) = -12.2$ kcal for the reaction $Li_2B_4O_7(cr) + 2\ HNO_3(aq) + 5\ H_2O(l) = 4\ H_3BO_3(aq) + 2\ LiNO_3(aq)$. Capps[1] Auxilliary data are from National Bureau of Standards Circular 500.[2]

Heat Capacity and Entropy

The enthalpy measurements of Smith[3] in the range 298 to 1190 K were smoothed graphically and used to determine C_p. A linear extrapolation of C_p was used from 1190 to 2000 K.

$S°(298.15\ K)$ was estimated by three routes: (1) $S°(Li_2B_4O_7, cr, 298.15\ K) = 37.3\ cal \cdot K^{-1} \cdot mol^{-1}$ based on JANAF $S°(Na_2B_4O_7, cr, 298.15\ K) = 45.3$ and $\Delta S°(2Na–2Li, 298.15\ K) = 8\ cal \cdot K^{-1} \cdot mol^{-1}$ from Latimer;[4] (2) $S°(Li_2B_4O_7, cr, 298.15\ K) = 36.7\ cal\ K^{-1} \cdot mol^{-1}$ in a similar manner based on $\Delta_f S°(2Na^+–2Li^+, 298.15\ K) = 8.6\ cal \cdot K^{-1} \cdot mol^{-1}$ from Kelley,[5] and (3) $S°(Li_2B_4O_7, cr, 298.15\ K) = 37.6\ cal \cdot K^{-1} \cdot mol^{-1}$ based on addition of the JANAF entropies for $2LiBO_2$ and B_2O_3. The value adopted is an average of these estimates.

Fusion Data

The value for T_{fus} is from Sastry and Hummel.[6] Rollet and Bouaziz[7] earlier reported $T_{fus} = 1188$ K. $\Delta_{fus} H° = 28.8\ kcal \cdot mol^{-1}$ is from Smith.[3]

PREVIOUS: December 1962 CURRENT: June 1965

$S°(298.15\ K) = [173.375]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1190 \pm 2\ K$

$\Delta_f H°(298.15\ K) = [-3317.715]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 120.5 \pm 6.3\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$(l, 298.15 K) is calculated from $\Delta_f H°$(cr, 298.15 K) by adding the enthalpy of fusion and the difference in enthalpy, $H°$(1190 K)–$H°$(298.15 K), between the crystal and liquid.

Heat Capacity and Entropy

The enthalpy measurements of Smith[1] in the range 296 to 1373 K were smoothed graphically and used to determine C_p. The C_p data have a discontinuity at about 756 K. A linear extrapolation of C_p was used from 1373 to 3000 K.

The entropy at 298.15 K is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

Refer to the crystal table for details.

PREVIOUS: CURRENT: June 1965

$S°(298.15\ K) = 51.92\ J·K^{-1}·mol^{-1}$
$T_{dcm} = [1100]\ K$

$\Delta_f H°(0\ K) = -104.7 \pm 8.4\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -105.0 \pm 8.4\ kJ·mol^{-1}$

Enthalpy of Formation

The equilibrium pressures (1169–1177 K) of the reaction $MgB_4(cr) \rightarrow Mg(g) + 4B(cr)$ were measured by Wright and Walsh.[1] The 3rd law value of $\Delta_r H°(298.15\ K)$ for this reaction is derived as $60.40 \pm 1.5\ kcal·mol^{-1}$. This leads to a $\Delta_f H°(298.15\ K) = -25.1 \pm 2.0\ kcal·mol^{-1}$ for $MgB_4(cr)$. The unit of equilibrium pressures reported should be in atmosphere not in mm Hg as printed. The diameter of the hole drilled through the center of the lid served as the effusion orifice should be 1/16 inch rather than the reported value 1/6 inch.

Heat Capacity and Entropy

The low temperature (17.34–299.53 K) heat capacities were measured by Swift and White.[2] Above 298.15 K the C_p values are estimated by comparison with those of other related borides. $S°(298.15\ K)$ was reported by Swift and White[2] using $S°(extrap., 20\ K) = 0.022\ cal·K^{-1}·mol^{-1}$.

Decomposition Data

T_{dcm} was estimated from the decomposition reaction reported by Wright and Walsh.[1]

$S°(298.15\ K) = 189.49\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1015.6\ K$

$\Delta_f H°(0\ K) = -3259.0 \pm 8\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -3276.7 \pm 8\ kJ·mol^{-1}$
$\Delta_{fus} H° = 76.9 \pm 6.3\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of the reaction $Na_2O(cr) + 2B_2O_3(l) \rightarrow Na_2B_4O_7(cr)$ was reported by Shartsis and Capps[1] from their enthalpy of solution measurements. Their values for the enthalpy of reaction of the oxides have been converted to the enthalpy of formation using JANAF values[2] for $B_2O_3(l)$ and for $Na_2O(cr)$. The above $\Delta_r H° = -85.2\ kcal·mol^{-1}$.

Heat Capacity and Entropy

In the low temperature region (5–344 K) the C_p values are those determined by Westrum and Grenier.[3] The enthalpy measurements of Smith[4] in the range 296 to 1015.6 K were smoothed graphically and used to determine C_p; the values did not join smoothly with those of Westrum and Grenier and the low temperature values were given greater weight. Above T_{fus} the heat capacity was extrapolated. $S°(298.15\ K)$ was derived from low temperature heat capacities.

Fusion Data

The value for T_{fus} is from Morey and Merwin.[5] Other reported values are: 1008 ± 5 K by Coles, Scholes, and Amberg;[6] 1011 K by Menzel;[7] 1005 K by Ponomareff;[8] 1015 K by Day and Allen;[9] and 1064 K by Burgess and Holt.[10] $\Delta_{fus} H°$ was obtained from the values of $\Delta_f H°$ for $Na_2B_4O_7(cr)$ and $Na_2B_4O_7(l)$ at 298.15 K as described above and the difference between $H°(1015\ K)$–$H°(298.15\ K)$ for crystal and liquid.

$S°(298.15\ K) = [194.636]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1015.6\ K$

$\Delta_f H°(298.15\ K) = [-3256.658]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 76.9 \pm 6.3\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of reaction $Na_2O(cr) + 2B_2O_3(l) \rightarrow Na_2B_4O_7(l)$ was reported by Shartsis and Capps[1] from their enthalpy of solution measurements. Their values for the enthalpy of reaction of the oxides have been converted to the enthalpies of formation using JANAF values[2] for B_2O_3(l) and Na_2O(cr). The above $\Delta_f H° = -80.4\ kcal·mol^{-1}$.

Heat Capacity and Entropy

The enthalpy measurements of Smith[3] in the range 298 to 1373 K, were smoothed graphically and used to determine C_p. These were joined smoothly with the low temperature data of Westrum and Grenier.[4] At 743 K a glass transition was observed and above this temperature the C_p adopted as constant.

The entropy at 298.15 K is calculated from that of the crystal by adding $\Delta_{fus}S°$ and the difference in entropy, $S°(1015\ K) - S°(298.15\ K)$, between the crystal and liquid.

Fusion Data

Refer to the crystal table for details.

PREVIOUS: CURRENT: March 1965

$S°(298.15\ K)$ = [166.9 ± 13] $J·K^{-1}·mol^{-1}$

$\Delta_f H°(0\ K)$ = Unknown

$\Delta_f H°(298.15\ K)$ = [−2858 ± 6] $kJ·mol^{-1}$

Enthalpy of Formation

See the PbB_2O_4(cr) table for the complete writeup. Evans[1] analysed the enthalpies of formation of lead borate system based upon Shartsis and Newman's enthalpies of solution and Mazzetti and DeCarli's phase studies. From the Shartsis and Newman paper Evans obtained the following:

$$PbO(cr) + 2B_2O_3(cr) \rightarrow PbO·2B_2O_3(gl) \qquad \Delta_r H = -11.9\ kcal·mol^{-1}$$

and estimated a $\Delta_f H°(298.15\ K)$ value of 11.4 $kcal·mol^{-1}$ for the conversion to the $PbO·2B_2O_3$(cr). With auxiliary JANAF values $\Delta_f H°(298.15\ K)$ is calculated to be −683.00 $kcal·mol^{-1}$.

Heat Capacity and Entropy

The heat capacity employed in this table is obtained by graphically smoothing the summation of the heat capacities of the constituent oxides.

The entropy at 298.15 K is obtained from a consideration of the entropies of sodium and calcium borates and those of the constituent oxides, as given by Kelley and King.[2] These indicate for the reaction:

$$MO·B_2O_3 + B_2O_3 \rightarrow MO·2B_2O_3$$

that the simple addition of entropies will give values at least 2.7 $cal·K^{-1}·mol^{-1}$ in case of Na borates and 5.7 $cal·K^{-1}·mol^{-1}$ for Ca borates too high for the reaction. The reason for this is probably structural, the $B_4O_7^{=}$ ion is a rigid chain of rings. It was assumed that additional B_2O_3 would extend the ring structure into a rigid plane and thus the average entropy difference of 4.2 for the reaction was assumed to hold for each additional mole of B_2O_3. Therefore the entropy at 298.15 K is obtained from $S°(298.15\ K)$ for PbB_2O_4 and B_2O_3 and the subtraction of 4.2 $cal·K^{-1}·mol^{-1}$.

PREVIOUS: December 1962 CURRENT: March 1965

$S°(298.15\ K) = 184.33\ J·K^{-1}·mol^{-1}$
$T_{fus} = 226.34\ K$

$\Delta_f H°(298.15\ K) = 42.84 \pm 6.7\ kJ·mol^{-1}$
$\Delta_{fus}H° = 6.134\ kJ·mol^{-1}$

Enthalpy of Formation

The vapor pressures of B_5H_9(l) were measured by Wirth and Palmer[1] and Johnston, Kerr, Clarke and Hallett.[2] By use of both the 2nd and 3rd law methods, the respective enthalpies of vaporization are evaluated. The $\Delta_f H°$(298.15 K) values for B_5H_9(l) are calculated from $\Delta_f H°$(298.15 K) for B_5H_9(g) and $\Delta_{vap}H°$(298.15 K) for B_5H_9(l) obtained previously.

Source	$\Delta_f H°$(298.15 K), kcal·mol^{-1} 2nd law	3rd law	$\Delta_f H°$(298.15 K) kcal·mol^{-1}
Wirth and Palmer[1]	7.26 ± 0.02	7.26	10.24 ± 1.6
Johnston, *et al.*[2]	7.23 ± 0.04	7.25	10.23 ± 1.6

The adopted value is the average of the two $\Delta_f H°$(298.15 K) values obtained.

Heat Capacity and Entropy

The heat capacities, 231.34–290.19 K, for B_5H_9(l) were measured by Johnston, Kerr, Clarke and Hallett.[2] The C_p values above 290.19 K are estimated by graphical extrapolation of the C_p curve plotted using the experimental data. The value of $S°$(298.15 K) was derived based on the low temperature C_p, 13.29–221.61 K, and $\Delta_{fus}H°$ for B_5H_9(cr) reported by Johnston, Kerr, Clarke and Hallett[2] and C_p values, 226.34–298.15 K, for B_5H_9(l), using $S°(13.29\ K) = 0.236\ cal·K^{-1}·mol^{-1}$ for B_5H_9(cr).

Fusion Data

The values of T_{fus} and $\Delta_{fus}H°$ were taken from Johnston, Kerr, Clarke and Hallett.[2]

Vaporization Data

The boiling point is calculated as the temperature at which the Gibbs energy change of the reaction $B_5H_9(l) \rightarrow B_5H_9(g)$ is zero. The enthalpy change of the reaction at T_{vap} is enthalpy of vaporization.

Enthalpy of Formation

The enthalpy change[2] of the reaction $B_5H_9(g) \rightarrow 5\ B(am) + 9/2\ H_2(g)$ was reported to be −12.99 ± 0.39 and −9.9 ± 1 kcal·mol^{-1} by Prosen, Johnson and Pergiel[1] and Gunn and Green,[2] respectively. Using $\Delta_f H°(298.15\ K) = 1.2 \pm 0.4$ kcal·mol^{-1} for the reaction $B(cr) \rightarrow B(am)$, the corresponding $\Delta_f H°(298.15\ K)$ values for $B_5H_9(g)$ were derived as 18.99 and 15.9 kcal·mol^{-1}. The adopted value is the average of these two.

Heat Capacity and Entropy

The molecular structure, a tetragonal pyramid of boron atoms, and constants were obtained from Hrostowski and Myers.[3] The vibrational frequencies were reported by Hrostowski and Pimentel.[4] The earlier models of pentaborane were assumed to have a hydrocarbon–like structure of low symmetry by Bauer and Pauling,[5] and Pitzer.[6] However, the electron diffraction and X–ray data by Hedberg, Jones and Schomaker,[7] and Dulmage and Lipscomb[8] revealed an unusual pyramidal structure of C_{4v} symmetry. The Raman spectrum of liquid B_5H_9 and the infrared spectrum of gaseous B_5H_9 from 3 to 25 microns have been obtained by Taylor, Beckett, Tung, Holden and Johnston.[9] The near infrared spectrum of $B_5H_9(l)$ have been examined at high resolution by Pondy and Beachell.[10] Ten bands were observed. The principal moments of inertia are: $I_A = 16.9101 \times 10^{-39}$, and $I_B = I_C = 11.8299 \times 10^{-39}$ g cm^2.

$S°(298.15\ K) = [251 \pm 13]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{dcm} = 1098\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -4633.53 \pm 10.4\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The enthalpy of reaction $K_2O(cr) + 3B_2O_3(l) \rightarrow K_2B_6O_{10}(cr)$ was reported by Shartsis and Capps[1] from their enthalpy of solution measurements. Their values for the enthalpy of reaction of the oxides have been converted to the enthalpies of formation using JANAF values[2] for $B_2O_3(l)$ and for $K_2O(cr)$. The above $\Delta_r H° = -122.8\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The enthalpy measurements of Smith[3] in the range 298 to 973 K were graphically smoothed and used to determine C_p. Above this range C_p is extrapolated.

The entropy at 298.15 K is obtained from a consideration of the entropies of sodium and calcium borates and those of the constituent oxides, as given by Kelley and King.[4] These indicate that for the reactions

$$MO + B_2O_3 \rightarrow MO \cdot B_2O_3 \qquad (1)$$

$$MO \cdot B_2O_3 + B_2O_3 \rightarrow MO \cdot 2B_2O_3 \qquad (2)$$

the simple addition of entropies will give values at least 2.7 $cal \cdot K^{-1} mol^{-1}$ too low for the reaction[1] and at least 2.7 $cal \cdot K^{-1} mol^{-1}$ too high for reaction[2]. The reason for this is probably structural, the $B_2O_4^{=}$ ion being a flexible chain while the $B_4O_7^{=}$ on probably is a rigid chain of rings. It was assumed that additional B_2O_3 would extend the ring structure into a rigid plane and thus the entropy difference for reaction[2] was assumed to hold for each additional mole of B_2O_3 added. Thus a value for $Na_2B_6O_{10}$ was estimated to be 55.5 ± 1.5 and then using an average value of 4.5 ± 1.5 $cal \cdot K^{-1} mol^{-1}$ for the difference between K_2 and Na_2 gave 60 ± 3 $cal \cdot K^{-1} \cdot mol^{-1}$ for the entropy fo $K_2B_6O_{10}$.

Decomposition Data

The incongruent melting point was given by Rollet[5] the decomposition products being $K_2B_4O_7(l)$ and $K_2B_8O_{13}(cr)$.

T_{dcm} = 1107 ± 4 K

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K)$ = −4659.89 ± 5.6 $kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of reaction $Li_2O(cr) + 3B_2O_3(l) \rightarrow Li_2B_6O_{10}(cr)$ was reported by Shartsis and Capps[1] from their enthalpy of solution measurements. Their values for the enthalpy of reaction of the oxides have been converted to the enthalpies of formation using JANAF values[2] for $B_2O_3(l)$ and $Li_2O(cr)$. The above $\Delta_r H° = -72.80\ kcal·mol^{-1}$.

Heat Capacity and Entropy

The enthalpy measurement of Smith[3] in the range 298 to 823 K were used to determine C_p. Above this range C_p is extrapolated. Entropy at 298.15 K is estimated from that of the component oxides and the difference from the oxides observed for twice $LiBO_2$(cr).

Decomposition Data

The incongruent melting point reported by Sastry and Hummel[4] is used here.

$S°(298.15\ K)$ = [203.3 ± 13] $J·K^{-1}·mol^{-1}$

$\Delta_f H°(0\ K)$ = *Unknown*

$\Delta_f H°(298.15\ K)$ = −4197 ± 8 $kJ·mol^{-1}$

Enthalpy of Formation

See the PbB_2O_4(cr) table for the complete writeup. Evans[1] analysed the enthalpies of formation of lead borate system based upon Shartsis and Newman's enthalpies of solution and Mazzetti and De Carli's phase studies. From the Shartsis and Newman paper Evans obtained the following:

$$PbO(cr) + 3B_2O_3(cr) \rightarrow PbO.3B_2O_3(gls) \quad \Delta_r H = -24.5\ kcal·mol^{-1}$$

and estimated a $\Delta_r H°(298.15\ K)$ of 16.0 $kcal·mol^{-1}$ for the conversion to the $PbO·3B_2O_3$(cr). With auxiliary JANAF values the $\Delta_f H°(298.15\ K)$ is calculated to be −1003.00 $kcal·mol^{-1}$.

Heat Capacity and Entropy

The heat capactiy employed in this table was obtained by graphically smoothing the summation of heat capacities of the constituent oxides.

The entropy at 298.15 K was obtained in the manner decribed in the PbB_4O_7 table from $S°(298.15\ K)$ for PbB_4O_7 and B_2O_3 and the subtraction of 4.2 $cal·K^{-1}·mol^{-1}$.

$S°(298.15\ K) = [293.7 \pm 16.7]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 1130\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15) = -5945.13 \pm 5.9\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 149.8 \pm 4\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The enthalpy of reaction $K_2O(cr) + 4\ B_2O_3(l) \rightarrow K_2B_8O_{13}(cr)$ was reported by Shartsis and Capps[1] from their enthalpy of solution measurements. Their values for the enthalpy of reaction of the oxides have been converted to the enthalpies of formation using JANAF values[2] for $B_2O_3(l)$ and $K_2O(cr)$.The above $\Delta_f H° = -137.00\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The enthalpy measurements of Smith[3] in the range 298 to 1130 K were smoothed graphically and used to determine C_p. Above this range C_p is extrapolated.

$S°(298.15\ K)$ is obtained by estimating the entropy of $Na_2B_8O_{13}(cr)$ as $65.7 \pm 2.5\ cal \cdot K^{-1} \cdot mol^{-1}$ as described on the table for $K_2B_6O_{10}(cr)$ and then using an average value of $4.5 \pm 1.5\ cal \cdot K^{-1} \cdot mol^{-1}$ for the replacement of Na_2 by K_2.

Fusion Data

T_{fus} is given by Rollet.[4] $\Delta_{fus} H°$ was obtained from the values of $\Delta_f H°$ for $K_2B_8O_{13}(cr)$ and $K_2B_8O_{13}(l)$ at 298.15 K reported above and the enthalpy of the crystal and liquid at T_{fus}.

PREVIOUS: March 1963 CURRENT: March 1965

$S°(298.15\ K)$ = [302.212] $J·K^{-1}·mol^{-1}$
T_{fus} = 1130 K

$\Delta_f H°(0\ K)$ = [−5897.253] $kJ·mol^{-1}$
$\Delta_{fus}H°$ = 149.8 ± 4 $kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of reaction $K_2O(cr) + 4B_2O_3(l) \rightarrow K_2B_8O_{13}(l)$ was reported by Shartsis and Capps[1] their enthalpies of solution measurments. Their values for the enthalpy of reaction of the oxides have been converted to the enthalpies of formation using JANAF values[2] for $B_2O_3(l)$ and for $K_2O(cr)$. The above $\Delta_f H° = -119.65$ kcal·mol^{-1}.

Heat Capacity and Entropy

The enthalpy measurements of Smith[3] in the range 298 to 1373 K on the glass and liquid were smoothed graphically and used to determine C_p. There is a discontinuity in the C_p curve, a glass transition at about 673 K. Above 673 K the C_p values were estimated to be constant.

The entropy is calculated from that of the crystal by adding $\Delta_{fus}S°$ and differences in entropy, $S°(1130\ K) - S°(298.15\ K)$, between the crystal and liquid.

Fusion Data

Refer to the crystal table for details.

$S°(298.15\ K) = [265.3 \pm 4]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{dcm} = 908 \pm 10\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15) = -5914.38 \pm 6.8\ kJ \cdot mol^{-1}$

Enthalpy of Formation

The enthalpy of the reaction $Li_2O(cr) + 4\ B_2O_3(l) \rightarrow Li_2B_8O_{13}(cr)$ was reported by Shartsis and Capps[1] from their enthalpy of solution measurements. Their values for the enthalpy of reaction of the oxides have been converted to the enthalpies of formation using JANAF values[2] for $B_2O_3(l)$ and for $Li_2O(cr)$. The above $\Delta_f H° = -73.35\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The enthalpy measurements of Smith[3] in the range 298 to 823 K were used to determine C_p. Above this range C_p is extrapolated. The entropy at 298.15 K is estimated from that of the component oxides and the difference from the oxides observed for twice $LiBO_2$(cr).

Decomposition Data

The incongruent melting point reported by Sastry and Hummel[4] is used here.

PREVIOUS: December 1962 CURRENT: March 1965

$S°(298.15\ K) = 176.56\ J·K^{-1}·mol^{-1}$
$T_{fus} = 371.93\ K$

$\Delta_f H°(0\ K) = 14.3 \pm 19\ kJ·mol^{-1}$
$\Delta_f H°(298.15) = -28.9 \pm 19\ kJ·mol^{-1}$
$\Delta_{fus} H° = 21.966 \pm 0.04\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy change of the reaction $B_{10}H_{14}(cr) \rightarrow 10\ B(am) + 7H_2(g)$ was reported to be 19.8 ± 1.4 and 18.0 ± 1.0 kcal·mol^{-1} by Johnson, Kilday and Prosen[1] and Gal'chenko, Timofeev and Skuratov,[2] respectively. Using $\Delta_f H°(298.15\ K) = 1.2 \pm 0.4$ kcal·mol^{-1} for the reaction $B(cr) \rightarrow B(am)$, the corresponding $\Delta_f H°(298.15\ K)$ values for $B_{10}H_{14}(cr)$ are calculated to be −7.8 and −6.0 kcal·mol^{-1}. The adopted value $\Delta_f H°(298.15\ K)$ for $B_{10}H_{14}(cr)$ is the average of these two.

Heat Capacity and Entropy

C_p(60 to 371.93 K) was given by Furukawa and Park.[3] The heat capacity above 371.93 K is estimated by comparison with that of the liquid decarborane. Heat capacity (14 to 205 K) was also reported by Kerr, Hallett and Johnston.[4] The value of $S°(298.15\ K)$ was taken from Furukawa and Park.[3]

Fusion Data

T_{fus} and $\Delta_{fus} H°$ were obtained from Furukawa and Park.[3]

Sublimation Data

$\Delta_{sub} H°(298.15\ K)$ is calculated from Gibbs energy functions and vapor pressure reported by Furukawa and Park.[3] Refer to the ideal gas table for details.

PREVIOUS: September 1962 CURRENT: December 1964

$S°(298.15\ K) = [234.935]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 371.93\ K$

$\Delta_f H°(298.15\ K) = [-7.133]\ kJ·mol^{-1}$
$\Delta_{fus}H° = 21.966 \pm 0.04\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(B_{10}H_{14}, cl, 298.15\ K)$ is calculated from $\Delta_f H°(B_{10}H_{14}, cr, 298.15\ K)$, by adding $\Delta_{fus}H°$ reported by and Park[1] and the enthalpy difference, $H°(371.93\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

C_p (371.93 to 380 K) was measured by Furukawa and Park.[1] Heat capacities below 371.93 and above 380 K were estimated by comparison with that of the gaseous decarborane. $S°(298.15\ K)$ is calculated from that of crystal in a manner analogous to the used for the enthalpy of formation.

Fusion and Vaporization Data

T_{fus} and $\Delta_{fus}H°$ were obtained from Furukawa and Park.[1] T_{vap} and $\Delta_{vap}H°$ are calculated from functions for $B_{10}H_{14}$(1) and $B_{10}H_{14}$(g).

Ground State Quantum Weight: [1] $\sigma = 2$

Point Group: C_{2v}

Bond Distances: B–B = 1.762 Å; B–B(apex) = 1.773 Å; B–H(bridge) = 1.394 Å; B–H = 1.256 Å

Bond Angles: B–B–B = 108°; H–B(apex)–B = 59° 34'; B–B–B(apex) = 60° 13'; B–H(bridge)–B = 46° 17'; B(apex–B–H) = 87° 42'; B(center)–B(center)–H = 120°

Product of the Moments of Inertia: $I_A I_B I_C = 8.657643 \times 10^{-113}\ g^3·cm^6$

Enthalpy of Formation

The vapor pressures of decaborane were measured by Furukawa and Park[1] and Miller.[2] The enthalpies of vaporization were derived by both the 2nd and 3rd law methods. Using the average value of $\Delta_{vap}H°$, the respective of enthalpies of formation for $B_{10}H_{14}$(g) are calculated.

Source	Reaction	$\Delta_r H°(298.15)$, kcal·mol^{-1} 2nd law	3rd law	$\Delta_f H°(298.15)$ kcal·mol^{-1}
1	$B_{10}H_{14}(cr) \rightarrow B_{10}H_{14}(g)$	16.63 ± 0.93	18.20	10.52 ± 4.5
	$B_{10}H_{14}(l) \rightarrow B_{10}H_{14}(g)$	13.28 ± 0.06	13.06	11.47 ± 4.5
2	$B_{10}H_{14}(cr) \rightarrow B_{10}H_{14}(g)$	17.81 ± 0.01	18.27	11.14 ± 4.5

The adopted value of $\Delta_f H°(298.15\ K)$ for $B_{10}H_{14}$(g) is the weighted average of the three $\Delta_f H°(298.15\ K)$ values listed in the above table.

Heat Capacity and Entropy

The molecular structure of $B_{10}H_{14}$(c) were reported by Kasper, Lucht and Harker,[3] Moore, Dickerson, and Lipscomb,[4] and Lipscomb.[5] For the calculation of the moments of inertia for $B_{10}H_{14}$(g) a simplified molecular model is adopted. The molecule is assumed to be composed of two regular pentagonal pyramids with a common base edge. The angle between the base planes of those pyramids is 73° 30'. Each of 10 H atoms is attached to a single B atom above the base plane. The remaining 4 H atoms, each bridge two B atoms. The vibrational frequencies were obtained from Evans,[6] which were derived based on the infrared and Raman spectra reported by Stewart[7] and Keller and Johnston.[8] The principal moments of inertia are: $I_A = 35.1322 \times 10^{-39}$, $I_B = 45.3594 \times 10^{-39}$, and $I_C = 54.3284 \times 10^{-39}\ g·cm^2$.

Lead Borate ($Pb_2B_{10}O_{17}$) CRYSTAL $M_r = 794.4898$

$\Delta_f H°(0\ K)$ = Unknown

$S°(298.15\ K) = [352.7 \pm 13]\ J \cdot K^{-1} \cdot mol^{-1}$ $\Delta_f H°(298.15) = -7087.7 \pm 13\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Refer to the PbB_2O_4(cr) table for the complete writeup. Evans[1] analysed the enthalpies of formation of lead borate system based upon Shartsis and Newman's enthalpies of solution and Mazzetti and DeCarli's phase studies. From the Shartsis and Newman paper Evans obtained the following:

$$2\ PbO(cr) + 5\ B_2O_3(cr) \rightarrow 2\ PbO \cdot 5B_2O_3(gls) \quad \Delta_r H = -45.2\ kcal \cdot mol^{-1}$$

and estimated a ΔH_{298} of 26.8 $kcal \cdot mol^{-1}$ for the conversion to the $2PbO \cdot 5B_2O_3$(cr). With auxiliary JANAF values the $\Delta_f H°(298.15\ K)$ is calculated to be $-1694.00\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The heat capacity employed in this table was obtained by graphically smoothing the summation of the heat capacities of the constituent oxides.

The entropy at 298.15 K was obtained in the manner described in the PbB_4O_7 table from the entropies of $PbO \cdot 2B_2O_3$ and $Pb \cdot 3B_2O_3$ and the subtraction of 4.2 $cal \cdot K^{-1} \cdot mol^{-1}$.

There have been no measurements reported for HBO which provide direct experimental information on its structure. However, the millimeter-wave spectra of the related species HBS[14] have been observed. These results show that this molecule is linear and has a B=S bond length which is 0.01 Å less than that for BS.[1] We assume a similar decrease in r_e(B=O) for the HBO–BO pair, and we obtain r_e(HB–O) = 1.19 Å with r_e(B=O) = 1.20 Å.[1] The H–B bond length is assumed the same as that for HBS.[14] Ab– initio calculations[8] of bond lengths for HBO by an optimization procedure predict values only slightly lower (~0.01 Å) than our estimates. We note that bond lengths computed by this procedure are normally slightly lower (~0.005 Å) than the true values as indicated by the results for HCP[16] and HBS.[17] By analogy with HBS,[14] we assume HBO to be linear. This assumption is in agreement with predictions from the Walsh diagram[15] for HAB molecules with ten valence electrons. In direct evidence available from product rule calculations[2] also tend to support a linear configuration.

calculation on HCN led these workers to conclude that their υ_2 values were probably lower (~50 cm^{-1}) than the true values. They suggested a better estimate of υ_2 as 690 ± 30 cm^{-1}. Pearson and McCormick[8] estimated υ_2 = 680 cm^{-1} from the l–doubling constant determined from their microwave measurements. These latter two values support our selection of υ_2 = 715 cm^{-1}. Photoelectron spectrometric results[10, 11] have led to predictions of υ_3 = 1100 cm^{-1} from the changes observed in vibrational frequencies produced upon ionization. We believe our calculated frequencies are uncertain to no more than ±50 cm^{-1} which amounts to an $S°$(298.15 K) error of ± 0.1 cal·K^{-1}·mol^{-1}.

Evidence is available which suggests that the ground state configuration and excited states of HBS are similar to those for the isoelectronic molecule HCP. Theoretical calculations[7, 12] predict the same ordering of valence orbitals for these two molecules. This orbital order is corroborated by the results[10, 11, and 13] of photoelectron spectroscopy where the similarity[11] in their PE spectra has been noted. In addition, we note that the Zeeman parameters recently reported for HBS and HCP by Pearson *et al.*[14] are nearly identical. We assume the same ground state configuration ($^1\Sigma^+$) for HBS as that for HCP,[3] and we estimate the electronic levels by analogy with those observed for HCP.

$\Delta_{trs} H° = [0.0]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 8.012 \pm 0.62\ kJ·mol^{-1}$

Enthalpy of Formation

Zero by definition.

Heat Capacity and Entropy

The adopted values below 298.15 K are based on $C_p°$(18–370 K) of Furukawa and Ishihara[1] and $C_p°$(1.5–20 K) of Roberts.[2] $S°$(298.15 K) is calculated from $C_p°$ based on an extrapolation of about 0.001 $cal·K^{-1}·mol^{-1}$ below 1.5 K. We estimate that $S°$(298.15 K) is uncertain by about 0.2 $cal·K^{-1}·mol^{-1}$, due mainly to possible effects of impurities. Furukawa and Ishihara[1] reported impurities (in mole %) of about 3% BaO, 1% Sr and 0.2% Ca. Further details on adjustment of the data for impurities are given in the original paper.[1]

Relative enthalpies were measured by Jauch,[3] Shpil'rain[4] and Ditmars and Douglas.[5] Earlier reviewers dismissed the abnormally high $C_p°$ values of Jauch as due to a very impure sample. The new data confirm this decision, but at least one new study[5] may also involve bias due to impurities. Separate portions from a common sample consisting of three Ba rods were used in the heat capacity study,[1] the enthalpy study[5] and the analytical studies.[1,5] The calorimetric data suggest variability in the impurity contents of the separate portions. The 2nd law study[4] used Ba which was not analyzed for O or N which are the most likely contaminants. Since the premelting effect in the enthalpy at 979 K appears to be 1/4 as large in[4] as in,[5] the sample of[4] may have been more pure; however, such a conclusion would be quite speculative. Liquid enthalpies are in reasonable agreement, but the crystal enthalpies of[4] are 4 to 20% lower than those of.[5] Another major difference is that[4] suggests a single "transition" near 650 K, while[5] suggests two "transitions" near 580 and 770 K. Further confusion arises because the enthalpies reported[4] for CsF(c, l) are unreasonably large.

We tentatively adopt the smoothed $C_p°$ of Ditmars and Douglas,[5] pending resolution of the transition discrepancy. The following alternative functions reproduce the enthalpies of Shpil'rain[4] and provide estimates of the possible bias in the adopted functions, Ba(α): $C_p°/cal·K^{-1}·mol^{-1} = 5.023 \pm 0.005657\ T$ (298–650 K), $\Delta_{trs} H° = 0.345\ kcal·mol^{-1}$ at 650 K; Ba(γ): $C_p°/cal·K^{-1}·mol^{-1} = 9.4$ (650–999.6 K), $\Delta_{fus} H° = 2.048\ kcal·mol^{-1}$ at 999.6 K; Ba(l): $C_p°/cal·K^{-1}·mol^{-1} = 10.0$ (999.6–1300 K). There is reasonable agreement between the alternative and adopted $C_p°$ for Ba(l) and Ba(γ), suggesting that the γ–phases are identical in the two studies. $C_p°(\alpha)$ from the equation is a reasonable extension of the data below 298.15 K;[1] $C_p°$ does not show the abnormally steep rise just above 300 K which appears in the enthalpy data[5] and to a lesser degree, in the $C_p°$ data.[1] The alternative functions suggest that the adopted γ–phase entropy may be biased by about +0.6 $cal·K^{-1}·mol^{-1}$ (about +6% in $S°(T)$–$S°$(298.15 K) due to impurities. Ditmars and Douglas stressed the possibility of such systematic errors[5] and estimated errors of up to 5% in $C_p°$ and $H°$. Our alternative functions suggest the maximum error in $C_p°(\alpha)$ may be much larger than 5%.

TransitionData

Recent data for Sr and Ca indicate that the pure metals exist in the fcc and bcc polymorphs but that impurities probably stabilize the hcp form. Although enthalpy data[4,5] suggest a similar controversy for Ba, the pure metal is usually reported to have the bcc form at all temperatures at atmospheric pressure.[6–9] Several high–pressure polymorphs are known.[10–12] Earlier literature[13] contains much evidence for a "transition" near 648 K at one atmosphere; this is consistent with new enthalpy data[4] and could correspond to the "transition" found by Bridgman[13] near 17 kbar at room temperature. Bridgman's "transition" is in dispute; it seems to involve a very small volume contraction[12,14] and no obvious change in X–ray pattern.[15] We speculate that these two "transitions" are identical; however, evidence for their being a property of pure Ba is inconclusive. The main support comes from the relatively small premelting effect in enthalpy.[4] The enthalpy data[4] are insufficient to distinguish whether the "transitions" is first or second order.

We tentatively adopt the two "transitions" with zero enthalpies selected by Ditmars and Douglas.[5] These values are placed in brackets to emphasize that there is no confirmatory evidence whatsoever. The authors suggest that these "transitions" may have resulted wholly from impurities. We speculate further the $T_{trs} = 582$ K could be due to impurity lowering of $T_{trs} = 650$ K, while $T_{trs} = 768$ K could result from crossing of a solid–solubility limit below the eutectic temperature of the Ba–BaO system. This case would favor the alternative functions given above. It is also possible that the Sr and Ca impurities could nucleate other polymorphs.

The adopted functions include $\Delta_{trs} H° = 0.97\ cal·mol^{-1}$ at 57 K from a small–anomaly observed between 50 and 60 K.[1]

Fusion and Sublimation Data

Refer to the liquid and ideal gas tables for details.

PREVIOUS: December 1970 CURRENT: December 1970

$S°(298.15\ K)$ = [66.328] $J·K^{-1}·mol^{-1}$
T_{fus} = 1000 ± 3 K

$\Delta_f H°(298.15\ K)$ = [4.985] $kJ·mol^{-1}$
$\Delta_{fus}H°$ = 8.012 ± 0.62 $kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of formation is calculated from that of the crystal by adding $\Delta_{fus}H°$ and the difference in enthalpy, $H°(1000\ K)–H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

$C_p°$ is based on the parabolic equation derived by Douglas and Krause[1] from enthalpy data of Ditmars and Douglas.[2] The enthalpy data (1003 to 1173 K) may be biased due to impurities in the sample;[2] however, enthalpy data (1035 to 1253 K) of Shpil'rain[3] are in reasonable agreement. This suggests that the large discrepancies for Ba(cr) are partially compensated by different values of $\Delta_{fus}H°$. Detailed discussions of the discrepancies and possible alternative functions are given on the crystal table. The alternative functions, derived from the possibly purer sample of Shpil'rain,[3] suggest that the adopted liquid entropies may be biased by about +0.4 $cal·K^{-1}·mol^{-1}$.

Douglas and Krause emphasized the uncertain nature[1] of the parabolic extrapolation of $C_p°$ from 1200 to 2000 K. The extrapolation is reasonable provided that the temperature coefficient of $C_p°$ is not grossly biased due to effects of impurities on the observed enthalpies. Such bias seems unlikely because of the agreement in enthalpy between samples of different purity[2,3] and because the impurities[2] are present in amounts much below their solubility limits[2,4,5] in Ba(l). We note also that $S°(2000\ K)$ is not significantly changed when the parabolic fit is replaced by a two–constant fit in which $C_p°$ approaches a constant (8.48 $cal·K^{-1}·mol^{-1}$) at high temperature.

The parabolic $C_p°$ is extrapolated to 580 K, the assumed glass transition temperature. $C_p°$ below 580 K is taken to be the same as the crystal. $S°(298.15\ K)$ is calculated in a manner analogous to that of the enthalpy of formation.

Melting Data

Ditmars and Douglas[2] considered early melting point data and arbitrarily selected 991 K. Recent data yield higher values of 998 ± 1[6,7] and 1002 ± 1 K.[8,10] These values represent more carefully purified samples. We adopt 1000 ± 3 K and adjust $\Delta_{fus}H°$ slightly so that the result is consistent with the smoothed enthalpy[2] of the liquid. Alternative functions based on enthalpies of Shpil'rain[3] suggest that the adopted $\Delta_{fus}H°$ may be too small by about 0.15 $kcal·mol^{-1}$ (see the crystal table).

Vaporization Data

T_{vap} = 2118.599 K is calculated as the temperature at which $\Delta_r G° = 0$ for Ba(l) → Ba(g). $\Delta_{vap}H°$ = 140.278 $kJ·mol^{-1}$ is the difference between $\Delta_f H°$(g) and $\Delta_f H°$(l) at T_{vap}. Bohdansky and Schins[11] ported T_{vap} = 2063 K(1 atm) based on extrapolation of their vapor pressure data from 2024 K. Our calculated T_{vap} is some 60 K higher due to the entropy difference between the adopted functions and vapor pressure data[11] and to adoption of the mean 3rd law $\Delta_{sub}H°$ rather than the apparent value at 2024 K. Refer to the ideal gas table for further details.

Enthalpy of Formation

$\Delta_f H°$ is $\Delta_{sub} H°$, 42.8 ± 1.2 $kcal·mol^{-1}$, selected from 3rd law analyses of pressure data tubulated below. The adopted value is from the recent boiling-point study of Bohdansky and Schins.[1] Except for the very scattered effusion data of Zavitsanos,[4] the other studies differ by unusually large amounts: −2,[2] −6[3] and +3 $kcal·mol^{-1}$.[5] Data of Ruff and Hartmann[3] are readily dismissed due to the large entropy discrepancy; their data for other metals have similar discrepancies. Data of Rudberg and Lempert[5] for Ca and Ba show almost identical biases, presumably due to poor effusion geometry or to impurities. A similar bias seems to exist in the effusion–resonance–fluorescence data of Hinnov and Ohlendorf:[6] our analysis is not tabulated below since the graphical data include large discrepancies in temperature. Hartmann and Scheider's Ba data[2] deviate considereably more from the selected value than do their data for Li, Mg, Ca and Sr. The differences probably arise from impurity effects. Since Ba is the least volatile of the reactive metals studied,[1,2] purification by distillation presents special problems. Even Bohdansky and Schins[1] noted that their Ba data may be biased by impurities.

Analyses of the pressure data assume that the monatomic gas is the only significant species in the vapor and that gas imperfection is negligible. Evidence supporting the unimportance of the dimer was reviewed by Douglas and Krause.[7] Estimated bond energies for the dimers of Mg, Ca, Sr nd Ba are less than 8.6 $kcal·mol^{-1}$.[8,10]

Source	Method	T/K[a]	$\Delta_f H°$(298.15 K), $kcal·mol^{-1}$ 2nd law	3rd law	δS $cal·K^{-1}·mol^{-1}$

[a]Temperature adjusted to IPTS–68 assuming published values to be IPTS–48.

Heat Capacity and Entropy

Observed energy levels and quantum weights are from Moore[11] as modified by Garton *et al.*[12,13] Additional levels above the cutoffs have been reported.[14,15] We adopt an energy–level cutoff which is about kTmax (Tmax = 6000 K) below each series limit. For Ba I this corresponds to omitting levels above 9s, 8p, 7d and 5f. Energies of unobserved but predicted terms[11] are estimated by comparison of Ca I, Sr I, Ba I and their isoelectronic ions. The most important are terms of the $5d^2$ configuration (20000–25000 cm^{-1}) and those of the 5d6s' configuration (estimated at 19000 ± 10000 cm^{-1}). Levels above 30000 cm^{-1} are averaged. The adopted functions are essentially identical with earlier tables up to 2000 K; however, the entropies at 6000 K differ as follows: Hilsenrath *et al.*,[16] 62.26; JANAF, 63.20; Gurvich *et al.*,[17] 63.65 $cal·K^{-1}·mol^{-1}$. These differences arise from different methods of cutoff and different degrees of accounting for the unobserved terms.

Enthalpy of Formation

$\Delta_f H°(Ba^+, g, 0 K)$ is calculated from $\Delta_f H°$(Ba, g, 0 K)[1] using the spectroscopic value of IP(Ba) = 42035.14 ± 0.05 cm^{-1} (502.8521 ± 0.0006 $kJ·mol^{-1}$) from Moore.[2] The ionization limit is converted from cm^{-1} to $kJ·mol^{-1}$ using the factor, 1 cm^{-1} = 0.01196266 $kJ·mol^{-1}$, which is derived from the 1973 CODATA fundamental constants.[3] Rosenstock *et al.*[4] and Levin and Lias[5] have summarized additional ionization and appearance potential data.

$\Delta_f H°(Ba^+, g, 298.15 K)$ is calculated from $\Delta_f H°$(Ba, g, 0 K) by using IP(Ba) with JANAF[1] enthalpies, $H°(0 K) - H°(298.15 K)$, for Ba(g), Ba^+(g), and e^-(ref). $\Delta_f H°(Ba \rightarrow Ba^+ + e^-, 298.15 K)$ differs from a room temperature threshold energy due to inclusion of these enthalpies and to threshold effects discussed by Rosenstock *et al.*[4] $\Delta H°$(298.15 K) should be changed by −6.197 $kJ·mol^{-1}$ of it is to be used in the ion convention that excludes the enthalpy of the electron.

Heat Capacity and Entropy

The information on electronic energy levels and quantum weights, given by Moore,[2,6] is incomplete because many theoretically predicted levels have not been observed. Although we have listed only the ground, the first four excited states, the highest observed excited state, and the ionization potential for Ba^+(g), all levels listed by Moore,[2,6] as well as estimated levels, are used in the calculation. The observed levels are too numerous to list completely. The calculations indicate that for Ba^+(g), the thermodynamic functions are independent of the estimated missing levels (for n = 6), the cut–off procedure, and the inclusion of n = 12 levels up to 6000 K. The reported uncertainty in $S°$(298.15 K) is due to uncertainties in the relative ionic mass, and the fundamental constants. Extension of these calculations above 6000 K may require consideration of the higher excited states (n>12), and use of different fill and cut–off procedures.[7]

Enthalpy of Formation

The selected value, $\Delta_f H°(0\ K) = -24.3\ kcal \cdot mol^{-1}$, is obtained from an analysis of spectroscopic data. Herzberg[1] suggested $D_0° = 2.8$ eV for BaBr(g) which was derived from a linear Birge–Sponer extrapolation of the ground state vibrational levels. Our adopted vibrational constants give 2.74 eV by a similar extrapolation. Based on the ionicity correction developed by Hildenbrand,[2] this value adjusts to 4.14 eV (95.5 $kcal \cdot mol^{-1}$) which is adopted. Gaydon[3] has claimed that the spectroscopic data for BaBr(g) are insufficient to obtain a reliable extrapolation. However, our adopted value for $D_0°$ gives $D_0°(BaBr)/\Delta_{at}H°(BaBr_2) = 0.48$ which is quite consistent with values of this ratio for other alkaline earth halide systems.[4] $\Delta_f H°(298.15\ K)$ corresponds to $-26.4\ kcal \cdot mol^{-1}$.

Ionic model calculations[5,6] have led to $D_0°$ values of 4.9 eV[5] and 3.76 eV[6]. The latter result is believed to represent a minimum value. Two other experimental values, which bracket the selected value, have been reported. Flame studies[7] gave $D_0° = 3.79$ eV, and chemiluminescence[8] from reaction of Ba atoms with Br_2 gave a lower limit to $D_0°$ of 4.54 eV. We assign an uncertainty of $\pm 10\ kcal \cdot mol^{-1}$ to $\Delta_f H°(0\ K)$ to include the possibility that these studies are correct.

Heat Capacity and Entropy

The value of r_e is obtained from that for gaseous $BaBr_2$[9] with $r_e(BaBr)/r_e(BaBr_2) = 0.96$. This value for the ratio is calculated from bond lengths[4] for several other alkaline earth halide systems. Two other estimates[5,6] of r_e agree with the adopted value to within 0.05 Å. The rotational constant is calculated from the estimated value for r_e. The value of α_e is obtained from a Morse potential function.

The vibrational constants are taken from the compilation of Rosen[10] and are corrected for the natural isotopic abundances of the elements. The observed electronic levels for BaBr(g) are from Rosen.[10] Also included are A, B, F, G, and H states. Their energies are estimated by analogy with those for SrBr(g).[9]

PREVIOUS: December 1974 (1 atm) CURRENT: December 1974 (1 bar)

$S°(298.15\ K) = [148.5 \pm 4.2]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1130 \pm 2\ K$

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = -757.7 \pm 1.7\ kJ·mol^{-1}$
$\Delta_{fus} H° = 31.96 \pm 0.63\ kJ·mol^{-1}$

Enthalpy of Formation

The selected value is based on results obtained from solution calorimetry performed in aqueous acid media. Ehrlich *et al.*[1] reported measurements of the enthalpies of solution of Ba(cr) and $BaBr_2$(cr) in HBr(555 H_2O). These results lead to $\Delta_f H°(BaBr_2, cr, 298.15\ K) = -181.1 \pm 0.4\ kcal·mol^{-1}$ ($-757.7 \pm 1.7\ kJ·mol^{-1}$) when combined with the most recent thermal data[2,3] for aqueous HBr. This value is adopted and is essentially that ($-181.0\ kcal·mol^{-1}$) which has been selected by NBS.[4]

Two independent calorimetric values in $kcal·mol^{-1}$ of -180.7[5] and -181.7[6] bracket our adopted value. These values are based on results of early enthalpy of solution measurements[5,6] which are combined with $\Delta_f H°(Ba^{+2}, aq, 298.15\ K) = -128.5\ kcal·mol^{-1}$ [4] and $\Delta_f H°(Br^-, aq, 298.15\ K) = -29.039 \pm 0.035\ kcal·mol^{-1}$.[2] Use of the newly derived value (see BaO(cr) table) for $\Delta_f H°$ of Ba^{+2}(aq) makes these values less negative by 0.5 $kcal·mol^{-1}$.

Heat Capacity and Entropy

$C_p°$ data needed to define $S°(298.15\ K)$ are unavailable. The adopted value $S°(298.15\ K) = 35.5 \pm 1.0\ cal·K^{-1}·mol^{-1}$ is a compromise between several estimates. JANAF[7] entropies for the other three barium dihalides suggest a value of $S°(298.15\ K)$ near $35.3\ cal·K^{-1}·mol^{-1}$ for the bromide. Application of the Berthelot principle[8] to the process $SrBr_2(cr) + Ba(cr) \rightarrow BaBr_2(cr) + Sr(cr)$ gives $S°(298.15\ K) = 36.7 \pm 1.7\ cal·K^{-1}·mol^{-1}$. Literature estimates which were considered are (in $cal·K^{-1}·mol^{-1}$) 35.0,[4] 35.5 ± 5.0,[9] and 38.[10]

The adopted $C_p°$ data are obtained from JANAF curve fits of the relative enthalpies (825–1130 K) reported by Efremova and Matizen.[11] For 27 enthalpy points the average deviation of the fit is ±0.4%; the maximum deviation is −1.0% at 847 K. Two points (1129 and 1130 K) are omitted from the fit, since these points presumably involve pre-melting effects. The derived value of $C_p°(298.15\ K) = 18.41\ cal·K^{-1}·mol^{-1}$ is supported by the value ($18.48\ cal·K^{-1}·mol^{-1}$) obtained from the process $BaCl_2(cr) + 2\ KBr(cr) \rightarrow BaBr_2(cr) + 2\ KCl(cr)$ with $\Delta C_p° = 0$. Relative enthalpies (487–1126 K) reported in equation form by Janz et al.[12] suggest a somewhat lower value ($17.8\ cal·K^{-1}·mol^{-1}$) for $C_p°$ at 298.15 K. Their smoothed enthalpies show deviations from our adopted ones that are generally less than ±0.3% but show maximum deviations of ±1.0% at 500 K and 900 K. The enthalpy measurement of Dworkin and Bredig[13] at the melting point ($T_{fus} \approx 1130$ K) is roughly 1% lower than that which is adopted. The values of $C_p°$ above T_{fus} are obtained from the adopted enthalpy equation.

Fusion Data

Refer to the liquid table for details.

Sublimation Data

$\Delta_{sub} H°(298.15\ K)$ is the difference in the values of $\Delta_f H°$ for the gas and crystal at 298.15 K.

PREVIOUS: CURRENT: December 1974

$S°(298.15\ K) = [172.108]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1130 \pm 2\ K$

$\Delta_f H°(298.15\ K) = [-730.193]\ kJ·mol^{-1}$
$\Delta_{fus}H° = 31.96 \pm 0.63\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ of the liquid is calculated from that of the crystal by adding $\Delta_{fus}H°$ and the difference in enthalpy, $H°(1130\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

$C_p°$ for the liquid is taken equal to 25.06 $cal·K^{-1}·mol^{-1}$ above the assumed glass transition temperature of 800 K. The constant value of $C_p°$ is derived from a curve fit of the relative enthalpies (1134–1963 K) reported by Efremova and Matizen.[1] For 11 enthalpy points the average deviation of the fit is ±0.3%; the maximum deviation occurs at 1386 K and amounts to −0.7%. Our adopted value for $C_p°$ is supported by the enthalpy measurements of Dworkin and Bredig[2] who found $C_p°(l) = 25.6\ cal·K^{-1}·mol^{-1}$. A considerably higher value (31 $cal·K^{-1}·mol^{-1}$) for $C_p°(l)$ is obtained from yet another enthalpy study;[3] however, these latter measurements extend over a relatively short temperature interval (~100 K) above T_{fus} and are probably insufficient to accurately establish $C_p°$ of the liquid. $C_p°$ data below the glass transition are those of the crystal.

$S°(298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

T_{fus} is the value determined in two independent drop–calorimetric investigations.[1,2] Nine other reported values for T_{fus} lie within 11 K of the adopted value. These other values are 1126 K,[3–5] 1119 K,[6,7] 1128 K[8] and 1120 K.[9–11]

$\Delta_{fus}H°$ is calculated as the difference between JANAF values for the enthalpies of the liquid and crystal at T_{fus}. Our value for $\Delta_{fus}H°$ is in excellent agreement with another drop–calorimetric value ($\Delta_{fus}H° = 7.63\ kcal·mol$)[2] and is further supported by a value ($\Delta_{fus}H° = 7.7\ kcal·mol^{-1}$)[4] obtained by dynamic differential calorimetry. Other published values include (in $kcal·mol^{-1}$) 7.75 ± 0.08,[1] 7.25 ± 0.19,[3] 7.15 ± 0.4,[4] and 7.0.[5]

Vaporization Data

T_{vap} is the temperature at which $\Delta_r G° = 0$ for the process $BaBr_2(l) = BaBr_2(g)$ at p = 1 bar. $\Delta_{vap}H°$ is the corresponding difference in the $\Delta_f H°$ values for the gas and liquid at T_{vap}. Petersen and Hutchison[12] calculated $T_{vap} = 2122$ K (p = 1 atm) from their measured vapor pressure data which covered the range 1175–1321 K. This value is considered somewhat uncertain due to the rather long extrapolation.

$S°(298.15\ K) = [342.1 \pm 8.4]\ J·K^{-1}·mol^{-1}$

$\Delta_f H°(0\ K) = -408.5 \pm 12.6\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -424.7 \pm 12.6\ kJ·mol^{-1}$

Vibrational Fequencies and Degeneracies ν, cm^{-1}
[160] (1)
[28] (1)
[223] (1)

Ground State Quantum Weight: [1] $\sigma = 2$
Point Group: C_{2v}
Bond Distance: Ba–Br = 2.99 ± 0.03 Å
Bond Angle: Br–Ba–Br = [150 ± 30]°
Product of Moments of Inertia: $I_A I_B I_C$ = [3.718284 × 10^{-112}] $g^3\ cm^6$

Enthalpy of Formation

The enthalpy of formation is calculated from the selected value for the enthalpy of vaporization, ($\Delta_{vap}H°(298.15\ K) = 73.04 \pm 0.24$ kcal·mol^{-1}, and the adopted value for $\Delta_f H°$(l). The selected value of $\Delta_{vap}H°$ is obtained from a 3rd law analysis of the vapor pressures for the liquid (1175–1321 K) reported by Peterson and Hutchison.[1,2] These measurements were made by the Knudsen effusion method on a sample of anhydrous $BaBr_2$ which had been prepared by direct union of high purity elements. The 2nd law $\Delta_{vap}H° = 73.7$ kcal·mol^{-1} is in agreement with the 3rd law value; thus, the entropy deviation is small ($\Delta_{vap}S°$(2nd law)–$\Delta_{vap}S°$(3rd law) = 0.5 ± 0.8 cal·K^{-1}·mol^{-1}). The dominant vapor species is assumed to be the dihalide monomer. This assumption is supported by the fact that negligible concentrations of polymeric species have been observed for some of the other alkaline–earth dihalides by use of mass spectrometry (see $CaBr_2$(g) table.[9]

A 3rd law analysis of a single sublimation pressure reported by Stock and Heynemann[3] leads to $\Delta_f H°(298.15\ K) = 104.3$ kcal·mol^{-1}. This result suggests a possible uncertainty in the adopted value for $\Delta_f H°$ of as much as ±3 kcal·mol^{-1}. This also brings our value in agreement with the selection (−105 kcal·mol^{-1}) of NBS.[4]

Heat Capacity and Entropy

Experimental evidence which has been presented in favor of a linear or nonlinear structure for $BaBr_2$ is conflicting. Electron diffraction analysis by Akishin and Spiridonov[5] showed $BaBr_2$ to be linear (180 ± 30°). Later studies by Klemperer *et al.*,[6,7] using electric quadrupole deflection of molecular beams, have shown that this molecule possesses a permanent dipole moment and therefore must be bent. A simple explanation of the observed trends in the geometries of the alkaline–earth dihalides as established by the electric deflection experiments[6,7] has been presented by Hayes,[8] and it appears quite likely that $BaBr_2$ is probably bent. The bond angle is arbitrarily taken to be greater than that for $BaCl_2$ (100°)[9] but less than that for BaI_2 (170°).[9] The bond distance is that measured in the gas phase by an electron diffraction study of Akishin and Spiridonov.[5] The principal moments of inertia are: $I_A = 228.6976 \times 10^{-39}$, $I_B = 221.3525 \times 10^{-39}$, and $I_C = 7.3451 \times 10^{-39}$ g cm^2. stretching force constant (K = 1.117 × 10^5 dynes/cm) is taken equal to that for BaBr.[9] The ratio of the stretching to bending force constants is estimated as 125. This value for the ratio is to be compared with that for BaF_2 (93)[9] and $BaCl_2$(1199).[9] The uncertainty in the adopted value for ν_2 is believed to be no greater than ±20 cm^{-1} which corresponds to roughly 1 cal·K^{-1}·mol^{-1} in the value of $S°(298.15\ K)$. Other sets[11–13] of estimated vibrational frequencies compare faavorably with ours; the maximum deviation is 35 cm^{-1} in ν_3.[13] The ground state quantum weight of one is assigned by analogy with that for $BaCl_2$.[9] Our Gibbs energy functions differ by roughly 2 cal·K^{-1}·mol^{-1} in the range 298–2000 K from those given by Brewer *et al.*[11] However, their values are based on a linear structure for the bromide which now appears to be incorrect.

Enthalpy of Formation

$\Delta_f H°$ is based mainly on two sets of gas–phase equilibria measured mass spectrometrically by Hildenbrand[1] and, to a lesser extent, on the analogous data of Potter *et al.*[2] Analyses of the mass–spectrometric data[1-3] are summarized below. The results from Potter *et al.*[2] and Zmbov[3] are less negative by about 4 kcal·mol^{-1}, suggesting the approximate uncertainty in $\Delta_f H°$. From the adopted $\Delta_f H°$ we derive $D_0° = 106.4 \pm 3$ kcal·mol^{-1}. Independent methods yield $D_0° = 103 \pm 5$,[4] ≥ 110,[5] 106.8 ± 2[6] and 105 ± 6 kcal·mol^{-1}.[6]

Electron–impact data[4] gave $D_0°$ (ClBa–Cl) = 115.8 ± 3.3 kcal·mol^{-1} and we use $\Delta_{at}H°(BaCl_2) = 219 \pm 4$ kcal·mol^{-1} to derive $D_0° = 103 \pm 5$ kcal·mol^{-1}. Chemiluminescence from crossed beams of Ba atoms with Cl_2 gave an approximate lower limit to $D_0°$ of 110 kcal·mol^{-1}.[5] Flame studies[6] gave $D_0° = 106.8 \pm 2$ kcal·mol^{-1} and $D_0°$ (ClBa–Cl) = 114 ± 4; we derive $D_0° = 105 \pm 6$ kcal·mol^{-1} from the latter value using $\Delta_{at}H°(BaCl_2) = 219$ kcal·mol^{-1}. Ryabova[6] considered the flames to involve $BaCl_2$, BaOHCl, and BaOH as well as BaCl. Schofield and Sugden[7] inferred that the flames involved mainly $BaCl_2$ rather than BaCl as assumed in earlier flame studies. Gaydon[8] discounted the values derived from electronic spectra, but Hildenbrand[1] showed that ionicity corrections bring the Birge–Sponer extrapolation into reasonable agreement with $D_0°$.

[a]Reactions: (A) Ba(g) + $BaCl_2$(g) → 2BaCl(g); (B) Ba(g) + AlCl(g) → BaCl(g) + Al(g).
[b]Data given in Table 2[3] are assumed to be $10^3 \times K_p$ instead of $10^4 \times K_p$.

Heat Capacity and Entropy

Electronic levels and vibrational constants are taken from the review of Rosen.[9] The level at 10351.1 cm^{-1} is T_0 rather than T_e. Vibrational constants are adjusted for natural isotopic abundances. B_e is calculated from r_e which is estimated by comparison of the bond lengths of MX_2(M=Mg, Ca, Sr, Ba and X=F, Cl) with those of MgCl, CaCl and MF(M=Mg, Ca, Sr, Ba). The value of α_e is estimated from the Morse potential function.

$\Delta_{fus} H° = 15.991 \pm 0.33\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is from NBS Technical Note 270–6[1] and its selection was discussed in detail by Parker.[2] The adopted value was derived by Ehrlich *et al.*[3] from their measurements of ΔH_{sol} of Ba(cr) and $BaCl_2$(cr) in HCl (550 H_2O). Earlier solution data for Ba[4] and $BaCl_2$[5, 6] are in good agreement,[2] but a recent study by Vorob'ev *et al.*[7] of Ba in HCl (240 and 400 H_2O) yields $\Delta_f H° = -201.8\ kcal \cdot mol^{-1}$. The deviation (+3.4 $kcal \cdot mol^{-1}$) from the adopted value is confirmed by direct measurements[7] of $\Delta_f H°$ and $\Delta_{sol} H°$ of BaH_2(cr), yielding $-202.1\ kcal \cdot mol^{-1}$ for $BaCl_2$(cr). All authors reported difficulties in obtaining or maintaining Ba and BaH_2 free of impurities; this provides conceivable reasons for bias in either of the opposing results. We assign an uncertainty of $\pm 3\ kcal \cdot mol^{-1}$ to include the possibility that Vorob'ev *et al.*[7] are correct but add an alternative of $\pm 0.6\ kcal \cdot mol^{-1}$ if their data are biased.

Parker[2] rejected $\Delta_f H° = -219.3\ kcal \cdot mol^{-1}$ obtained by Siemonsen[8] by direct chlorination and $\Delta_f H° = -212.0\ kcal \cdot mol^{-1}$ which would result from BaO(cr) based on Mah's direct combustion.[9] Parker noted that these more negative values are incompatible with data for BaO_2, $Ba(OH)_2$ and $BaCO_3$. They are also incompatible with calorimetric data for BaH_2 noted above and equilibrium data as discussed on the tables for $BaCl_2$(l and g).

Heat Capacity and Entropy

$C_p°$ is based on adiabatic calorimetry (6–346 K) of Goodman and Westrum.[10] $S°$ is calculated from $C_p°$ using $S°(6\ K) = 0.012\ cal \cdot K^{-1} \cdot mol^{-1}$. $C_p°$ above 300 K is from constrained fitting of enthalpy data (340–1197 K for α–phase and 1201–1231 K for β–phase) measured in an ice calorimeter by Gardner and Taylor.[11] The sample studied at high temperatures was a portion of that used at low temperatures. Deviations of the H data[11] from the adopted values are <0.1% for most points but show a maximum of −0.3% for two points near 400 K.

Other enthalpy studies include those of Dworkin and Bredig,[12] Janz et al.[13] and Gant.[14] Deviations from the adopted values are about +2% for the smooth values (~1100–1230 K) of,[12] +1.8 to +2.9% for the equations (892–1235 K) of,[13] and −1.7 to +6.7% for the data (406–1230 K) of.[14] Popov and Gal'chenko[15] used a continuous heating method to obtain $C_p°$ values which deviate by +4 to +9% (443–973 K).

Transition Data

T_{trs} = 1198 K is from the enthalpy study of Gardner and Taylor.[11] Other enthalpy studies gave 1193[12] and 1198 K,[13] while thermal analysis gave 1199[16] and 1197 K.[17] $\Delta_{trs} H°$ is calculated from our adopted fits of the enthalpy data.[11] Published values include 4.04,[11] 4.10[12] and 4.15 ± 0.16.[13]

Fusion Data

Refer to the liquid table for details.

Sublimation Data

Refer to the ideal gas table for details.

PREVIOUS: CURRENT: December 1972

$S°(298.15\ K) = [143.518]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1235 \pm 1\ K$

$\Delta_f H°(298.15\ K) = [-832.467]\ kJ·mol^{-1}$
$\Delta_{fus}H° = 15.991 \pm 0.33\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is calculated from that of the crystal by addition of $\Delta_{fus}H°$ and the difference in enthalpy, $H°(1235\ K)-H°(298.15\ K)$, between crystal and liquid. Independent values of $\Delta_f H°$ for liquid (and crystal) may be derived from equilibrium data[1,2] for $Ca(l) + BaCl_2(l) \rightarrow Ba(l) + CaCl_2(l)$. Our 3rd-law analysis is summarized below; it shows that the data of Feschotte–Ostertag[1] are consistent with the adopted $\Delta_f H°(cr) = -205.2\ kcal·mol^{-1}$ from Ehrlich *et al.* (cf. $BaCl_2$, cr), while the data of Peterson and Hinkebein[2] are more consistent with the alternative $\Delta_f H°(cr) = -201.8\ kcal·mol^{-1}$ from Vorob'ev *et al.* Both are incompatible with $\Delta_f H°(cr) = -219.3$ from direct chlorination and $\Delta_f H°(cr) = -212.0$ derived from Mah's $\Delta_c H$ value for $\Delta_f H°$ of BaO(cr).

1	Indirect via $SrCl_2$	1273	14.12 ± 1.8		−199.1 ± 2	−205.4 ± 2
2	Direct measurement	1173–1223	−2.5 ± 8.1	11.47 ± 0.6	−196.5 ± 1	−202.7 ± 1

Heat Capacity and Entropy

The constant $C_p° = 26.0\ cal·K^{-1}·mol^{-1}$ is based on enthalpy data (1238–1347 K) measured in an ice calorimeter by Gardner and Taylor.[3] Deviations of the data from the adopted fit are all less than 0.05%. Smoothed enthalpies of Dworkin and Bredig[4] deviate by +1.2% and those of Janz *et al.*[5] by +2.7 to 2.1%. Enthalpy data of Gant[6] deviate by +1.5%. $C_p°$ is taken equal to that of the crystal from 298 to 800 K, the assumed glass transition. $S°$ is calculated in a manner analogous to that used for $\Delta_f H°$.

Fusion Data

T_{fus} is from the enthalpy study of Gardner and Taylor.[3] Some other reported values include 1233[4] and 1235 K[5,6] from enthalpy studies and 1234[7] and 1235 K[8] from thermal analysis. $\Delta_{fus}H°$ is obtained from the difference in the adopted enthalpy fits for liquid and β-phases. Published values include 3.82,[3] 3.90[4] and 4.13 ± 0.12[5] $kcal·mol^{-1}$.

Vaporization Data

T_{vap} is calculated as the temperature at which $\Delta_r G° = 0$ for $BaCl_2(l) \rightarrow BaCl_2(g)$ at p=1 bar. $\Delta_{vap}H°$ is calculated as the corresponding $\Delta_r H°$.

Bond Distance: Ba–Cl = 2.82 ± 0.03Å

Bond Angle: Cl–Ba–Cl = [100 ± 20]°

Product of the Moments of Inertia: $I_A I_B I_C = 1.128013 \times 10^{-112}\ g^3 cm^6$

Enthalpy of Formation

$\Delta_f H°(298.15\ K)$ is calculated from $\Delta_f H°(cr)$ by addition of $\Delta_{sub} H° = 86.0 \pm 1.5\ kcal \cdot mol^{-1}$ derived from 3rd law analysis of the vapor–pressure equation of Hildenbrand *et al.*[1,2] The equation[1] summarized five torsion–effusion runs (83 total points) and is reasonably consistent with five boiling pressures in the mmHg range measured by Novikov.[3] Other vapor pressure data[4-6] reviewed below are considered less reliable. $\Delta_f H°(g)$ is assigned alternative uncertainties to reflect the discrepancies in $\Delta_f H°(cr)$. Equilibria derived from flame studies[7] yield $\Delta_f H°(g) = -119.1 \pm 3$ and $\Delta_f H°(cr) = -205.1 \pm 3\ kcal \cdot mol^{-1}$, which confirm the adopted values by an independent path. Mass spectra[8] at 1230 K showed that the saturated vapor consists predominantly of $BaCl_2$ with considerably less than 1% of dimer.

[a]Pressures obtained from an equation summarizing 5 runs (83 total points).

[b]$\Delta_r H°$ for Ba(g) + 2 HCl(g) → BaCl(g) + 2 H(g) yields $\Delta_f H°(298.15\ K) = 119.1 \pm 3\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

Vibrations ν_1 and ν_2 are the values quoted by Hildenbrand[9] and derived from IR spectra of molecules in matrix isolation.[10] The bending mode was not observed; its value was calculated[10] from force–constant correlations as described for BaF_2.[11] Hastie *et al.*[12] assigned the bending mode to a band which they observed at 61 cm^{-1} in argon and 62 cm^{-1} in neon. This value would reduce $S°$ by about 1.0 $cal \cdot K^{-1} \cdot mol^{-1}$. Our assigned uncertainty includes this possibility. Agreement is better for $\nu_1 = 255$[9,10] or 262 cm^{-1} (in Ne)[12] and for $\nu_3 = 265 \pm 5$ (gas)[13], 260[9,10] or 268 cm^{-1} (in Ne).[12] We adopt the gas–phase value[13] for ν_3.

Bond length is from gas–phase electron diffraction[14] which also gave the bond angle 180° ± 40°. Later studies[15] of electric and magnetic deflection of molecular beams revealed a permanent electric dipole moment and suggested a bond angle of the order of roughly 120°. Hastie *et al.*[12] estimated an angle of 120° ± 10° from relative intensities of ν_1 and ν_3. The matrix spectra[9,10] were first interpreted to give an angle of 120° but reanalysis by Hemple[10] gave the angle 95.4°, estimated from the three fundamentals. We adopt 100° ± 20° and note that $S°$ changes by only 0.2 $cal \cdot K^{-1} \cdot mol^{-1}$ in the range 95° to 120°. The singlet ground state is based on magnetic deflection data.[15] The principal moments of inertia are $I_A = 25.5142 \times 10^{-39}$, $I_B = 54.9471 \times 10^{-39}$, and $I_C = 80.4613 \times 10^{-39}\ g \cdot cm^2$.

Enthalpy of Formation

$\Delta_f H°$ is obtained from a 3rd law analysis of K_p data for three gaseous dissociation equilibria. The K_p data were derived from observations made on the condensed phase systems BaF_2–B^1 and BaF_2–Al^2 by the mass spectrometric–Knudsen effusion method. Results of a 2nd and 3rd law analysis of these data are given below. Also included below are results derived from two mass spectrometric studies[2, 3] of the heterogeneous reaction (D), and a value for the heat of dissociation of BaF which was determined from spectrophotometric studies[4, 5] of reaction equilibria in H_2–O_2–N_2 flames.

Reactions: (A) $Ba(g) + BaF_2(g) \rightarrow 2\ BaF(g)$ (D) $2\ BaF(g) \rightarrow Ba(g) + BaF_2(cr)$
(B) $2Ba(g) + BF_3(g) \rightarrow 2\ BaF(g) + BF(g)$ (E) $BaF(g) \rightarrow Ba(g) + F(g)$
(C) $Ba(g) + AlF(g) \rightarrow BaF(g) + Al(g)$

[a]One point rejected due to failure of a statistical test.

It is believed that the K_p data for the three homogeneous reactions (A, B, and C) are more reliable than those for the heterogeneous reaction (D) due to the need for a machine calibration constant which appears in the equilibrium expression for the latter. Ehlert *et al.*[2] determined this constant from vaporization experiments performed with silver contained in their Knudsen cell. Further support for this belief is provided by the large positive drift that arises in the 3rd law analysis of these K_p's. Also, it is felt that the results otained from the flame–spectrophotometric studies[4, 5] are somewhat more uncertain than those derived from the K_p data for the three homogeneous reactions. Therefore, we choose to adopt a median value $\Delta_f H°(BaF, g, 298.15\ K) = -77.0 \pm 2.0\ kcal·mol^{-1}$ of the first three results. The adopted value corresponds to a dissociation energy of $D_0°$ (Ba–F) = 137.9 $kcal·mol^{-1}$ (5.98 eV).

Gaydon[7] has reported a spectroscopic value for $D_0°$ of 3.8 eV which is considerably lower than the adopted thermochemical value. The spectroscopic value is based on a linear Birge–Sponer extrapolation of the thirteen known vibrational levels for the ground state ($^2\Sigma^+$). However, Gaydon[7] and later Hildenbrand[8] have shown that the linear extrapolation generally under–estimates $D_0°$ when the bonding in the molecule is partially ionic. Correcting $D_0°$(LBX) for the ionic character of BaF with the ionicity parameter suggested by Hildenbrand,[8] we obtain $D_0°$ (Ba–F) = 6.9 eV which is somewhat high. Other values for $D_0°$ that have been reported are 5.94[1] and 5.68 eV.[9] Both of these values were calculated from the Rittner ionic model[10] for polarizable ions and show remarkably good agreement with the adopted value.

Heat Capacity and Entropy

The spectroscopic data, except for α_e, are given by Rosen[11] for ^{138}BaF. α_e is calculated from the Morse potential function. Corrections to these data to account for the natural isotopic abundances of barium were found to be negligible. The electronic states and levels are also taken from the compilation of Rosen.[11]

Enthalpy of Formation

The appearance potential (AP) of BaF^+ from BaF(g) has been measured mass spectrometrically as 4.9 eV[1] and 4.8 ± 0.3 eV.[2] This latter value has been confirmed by Zmbov and Margrave.[3] Combining these results with $\Delta_f H°$(BaF, g, 0 K) = −76.5 ± 2.0 kcal·mol^{-1},[4] we obtain $\Delta_f H°$(BaF^+, g, 0 K) equal to 36.5 and 34.2 ± 9.0 kcal·mol^{-1}.

Hildenbrand[2] also reported an AP for BaF^+ from BaF_2(g) as 13.5 ± 1.0 eV. Green *et al.*[5] obtained an ionization efficiency curve for BaF^+ which extrapolates (high-energy portion) to 12.9 eV at zero ion current. Assuming the process to be $e^- + BaF_2(g) \rightarrow BaF^+(g) + F(g) + 2e^-$, we obtain $\Delta_f H°$(BaF^+, g, 0 K) values of 101.3 ± 25 and 87.5 kcal·mol^{-1} by combining the above results with $\Delta_f H°$(BaF_2, g, 0 K) = −191.6 ± 1.5 kcal·mol^{-1} and $\Delta_f H°$(F, g, 0 K) = 18.36 ± 0.4 kcal·mol^{-1}.[4]

The two lower values for $\Delta H°$(0 K) are preferred here, since the dissociative ionization of BaF (g) most likely involved unknown kinetic energy factors. We choose to adopt $\Delta_f H°$(BaF^+, g, 0 K) = 35.0 ± 10.0 kcal·mol^{-1} which gives $\Delta_f H°$(BaF^+,g, 298.15 K) = 35.9 ± 10.0 kcal·mol^{-1}. The adopted heat of formation corresponds to an ionization potential for BaF(g) of 4.83 eV.

Heat Capacity and Entropy

The dissociation energy of BaF^+($D_0°$ = 145.4 kcal·mol^{-1}) is slightly greater than that for BaF($D_0°$ = 137.9 kcal·mol^{-1})[4] which implies somewhat stronger bonding in the ion. Thus, one would expect the internuclear distance (r_e) for the ground state of BaF^+ to be less than that for BaF. Barrow and Beale[6] postulated from a rotational analysis of the $F^2\Sigma^+$–$X^2\Sigma^+$ band system of SrF a r_e for SrF^+ which was some 4% lower than that for SrF. We assume a similar decrease in r_e for BaF^+ and obtain r_e = 2.064 Å from r_e(BaF) = 2.152 Å.[4] ω_e is calculated from Badger's rule[7] which can be written in the form $\omega_{e2} = 3.159 \times 10^6/\mu(r_e - d_{ij})$.[3] Molecular data for CsF,[4] BaF,[4] and BaO[8] were used to determine the constant d_{ij}. The product $x_e\mu^{1/2}$ has been shown to be constant within a group of similar molecules by Barrow and Caunt.[9] Since $\mu^{1/2}(BaF^+) \cong \mu^{1/2}$(BaF), we assume $x_e(BaF^+) = x_e$(BaF) and obtain $\omega_e x_e$ equal to 2.06 cm^{-1} with our estimated value for ω_e. α_e is obtained from the other constants assuming a Morse potential function.

BaF has eight valence electrons; thus, the ground state configuration ($^1\Sigma^+$) and electronic levels for the A and B states are estimated from those for the isoelectronic molecule BaS.[10] By analogy with the gaseous alkaline earth oxides,[11] C_2,[4] and BeS,[12] low-lying triplet states are to be expected. The two estimated triplet levels are based on those which have been observed directly in C_2,[4] BeS,[12] and indirectly (through perturbative effects) in BaS.[10] Also included are a $^1\Pi$ state at 11,000 cm^{-1} and $^1\Delta$ state at 13,000 cm^{-1}. These levels are also estimated by analogy with those for C_2[4] and BeS.[12] It is believed that our adopted electronic entropies for BaF^+ are most likely minimal values. Probable upper limits for the electronic contributions can be established by decreasing the triplet levels to 1000 cm^{-1} ($^3\Pi$) and 5000 cm^{-1} ($^3\Sigma$) and neglecting the other excited states. This increases the entropy (in cal·K^{-1}·mol^{-1}) by 3.8 and 2.1 at 2000 K and 4000 K, respectively.

$S°(298.15\ K) = 96.40 \pm 0.42\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{trs} \approx 1240\ K\ (\alpha \rightarrow \beta)$
$T_{trs} \approx 1480\ K\ (\beta \rightarrow \gamma)$
$T_{fus} \approx 1641\ K$

$\Delta_f H°(0\ K) = -1207.5 \pm 4.2\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -1208.8 \pm 4.2\ kJ \cdot mol^{-1}$
$\Delta_{trs} H° = 0.0\ kJ \cdot mol^{-1}$
$\Delta_{trs} H° \approx 2.674 \pm 0.837\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 23.359 \pm 0.628\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Guntz[1] measured the heat of neutralization of $Ba(OH)_2$(aq) with HF(aq) as $\Delta H = -34.8\ kcal \cdot mol^{-1}$ at 284 K. We estimate $\Delta C_p = 106\ cal \cdot K^{-1} \cdot mol^{-1}$[2] for $Ba(OH)_2\ 660\ H_2O + 2(HF\ 110\ H_2O) \rightarrow BaF_2(cr) + 2\ H_2O(l)$ which gives $\Delta_r H°(298.15\ K) = -33.4\ kcal \cdot mol^{-1}$. This leads to $\Delta_f H°(298.15\ K) = -288.3\ kcal \cdot mol^{-1}$ when combined with auxiliary data.[3,4,5] Petersen[6] investigated the same reaction but with HF·200 H_2O and found that 16% of the BaF_2 remained dissolved. After correcting for incomplete precipitation his final result was $\Delta H°(292.15\ K) \approx -33.92\ kcal \cdot mol^{-1}$ which gives $\Delta_f H°(298.15\ K) = -288.2\ kcal \cdot mol^{-1}$.

In the same study, Petersen[6] measured the heat of precipitation of BaF_2 from $BaCl_2$(aq) with AgF(aq) as $\Delta H°(292\ K) = -35.02\ kcal \cdot mol^{-1}$. We estimate $\Delta C_p = 108\ cal \cdot K^{-1} \cdot mol^{-1}$[2] for $2\ (AgF \cdot 200\ H_2O) + BaCl_2 \cdot 400\ H_2O \rightarrow BaF_2(cr) + 2AgCl(cr)$ which gives $\Delta H°(298.15\ K) \approx -34.4\ kcal \cdot mol^{-1}$. Using auxiliary data,[4,7] we obtain $\Delta_f H°(BaF_2, cr, 298.15\ K) \approx -288.4\ kcal \cdot mol^{-1}$. Petersen[6] also reported the heat of solution of BaF_2 as $\Delta_{sol} H° = 1.88\ kcal \cdot mol^{-1}$. From this result, we obtain $\Delta_f H°(298.15\ K) \approx -290.3\ kcal \cdot mol^{-1}$.

Stephen and Stephen[9] have selected a "best" value for the solubility of BaF_2 of 1.614 g/l at 298.15 K which corresponds to $K_{sp} \approx 3.1196 \times 10^{-6}$. Using $\Delta_f G°$ (Ba^{+2}, ∞ aq, 298.15 K) = −134.02[4] and $\Delta_f G°(F^-, \infty\ aq, 298.15\ K) = -66.96\ kcal \cdot mol^{-1}$,[1,5] we calculate $\Delta_f G°(298.15\ K) = -275.45\ kcal \cdot mol^{-1}$. Based on the adopted functions, $\Delta_f H°(298.15\ K) = -287.5\ kcal \cdot mol^{-1}$.

Two equilibrium studies[10,11] have also been reported. 2nd and 3rd law analyses of these data are given below.

Source	Reaction	T/K	No. of Points	$\Delta_f H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	Drift cal·K^{-1}·mol^{-1}	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}
Domangem[10]	A	1173–1373	3	41.0	62.5 ± 3.4	16.9 ± 1.0	−267.3
Hood and Woyski[11]	B	477–1033	9	5.9	5.8 ± 1.0	−0.1 ± 0.1	−279.8

Reaction: (A) $BaF_2(cr) + H_2O(g) \rightarrow 2\ HF(g) + BaO(cr)$ (B) $HF(g) + 0.5\ BaCl_2(cr) \rightarrow HCl(g) + 0.5\ BaF_2(cr)$

The large discrepancy which arises in the $\Delta_f H°$values obtained from the equilibrium and calorimetric results is not well understood. Domange[10] has measured similar equilibria for CoF_2, MgF_2, and CaF_2 which are very consistent with JANAF heats of formation. Very recently, Finch *et al.*[12] attempted to determine the heat of precipitation of BaF_2 form $BaCl_2$(aq) by dissolving a slight excess of NaF. X-ray diffraction studies of the precipitate showed the formation of BaClF and Ba_2ClF_3along with BaF_2. We believe the equilibrium results of Hood and Woyski[11] may have been influenced by the formation of mixed halides. Also, it seems quite likely that the calorimetric results of Petersen[6] on the precipitation of BaF_2 from $BaCl_2$(aq) with AgF(aq) would be similarly influenced. We adopt $\Delta_f H°(298.15\ K) = -288.9 \pm 1.0\ kcal \cdot mol^{-1}$ which is a weighted value of the calorimetric results of Guntz[1] and Petersen[6] on the heat of neutralization of $Ba(OH)_2$(aq), the heat of solution of BaF_2(cr)[6] and the K_{sp} value obtained from the solubility data of Stephen and Stephen.[9] Barany *et al.*[8] determined the heat of solution of BaO(cr) in HF(aq), which contained some dissolved silica, as $\Delta H° = -73.04\ kcal \cdot mol^{-1}$. We assume this value refers to the reaction $BaO(cr) + 2\ HF \cdot 4.41\ H_2O \rightarrow BaF_2(cr) + H_2O(l)$, and we calculate $\Delta_f H°(298.15\ K) = -290.2 \pm 2.0\ kcal \cdot mol^{-1}$with $\Delta_f H°(BaO, cr, 298.15\ K) = -132.3\ kcal \cdot mol^{-1}$.[5] These results substantiate our adopted $\Delta_f H°$ value.

Heat Capacity and Entropy

C_p below 298 K is based on the low temperature (14–300 K) heat capacities of Pitzer *et al.*[13] These data show an unusual leveling off of C_p above 274 K, and values in the range 274–300 K are obtained by graphical extrapolation of their low temperature data. $S°(298.15\ K)$ is based on the adopted C_p's with $S°(15\ K) = 0.09\ cal \cdot K^{-1} \cdot mol^{-1}$.

Relative enthalpies have been reported by Efremova and Matizen (757–2053 K)[14] and Krestovnikov and Karetnikov (288–1273 K).[15] The enthalpy data of Efremova and Matizen[14] indicated the existence of a second order phase transition at 1240 K. We adopt their smoothed C_p data for 800–1480 K. C_p's below 800 K are estimated graphically by comparison with those for $BaCl_2$, CaF_2, and SrF_2.[5] C_p (BaF_2, γ) are based on a JANAF curve fit of their relative enthalpies (1482–1596 K). The rapid rise in the enthalpy near the melting point is assumed to be due to premelting, and these points were not used in the fit. The maximum deviation of our adopted functions from those used in the fit is 0.5%. Kelley[16] analyzed the enthalpy data of Krestovnikov and Karetnikov.[15] His smoothed enthalpies are consistently 2–3% higher than those adopted. No second order phase transition was observed. These data are judged to be less reliable and are not used in our evaluation.

Transition Data

The transition temperatures are those reported by Efremova and Matizen.[14] We assume the transition at 1240 K is of the second order type, since no discontinuity appears in their enthalpy data at this temperature. The heat of the β–γ transition is calculated as the difference between the adopted enthalpies for these two phases at 1480 K.

Continued on page 358

$S°(298.15\ K) = [121.254]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 1641\ K$

$\Delta_f H°(298.15\ K) = [-1171.294]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 23.359 \pm 0.628\ kJ·mol^{-1}$

Enthalpy of Formation

The enthalpy of formation of the liquid is calculated from that of the crystal by addition of $\Delta_{fus}H°$ the difference in enthalpy, $H°(1641\ K)-H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

A glass transition is assumed at 1100 K below which $C_p°$ follows that of the crystal. $C_p°$ is assumed constant in the temperature range 1100–3500 K and is based on a JANAF curve fit of the relative enthalpies of Efremova and Matizen[1] for the liquid (1641–1900 K). Some scatter was observed in these data at the higher temperatures, and these points were not included in the fit. The maximum deviation of the observed enthalpies which were used in the fit from those adopted is 0.29%.

$S°(298.15\ K)$ is calculated in a manner analogous to that used for the enthalpy of formation.

Fusion Data

T_{fus} is the value selected by Efremova and Matizen[1] from their relative enthalpy data. These data show premelting starting near 1620 K and complete melting occurring at 1646 K. Other values for T_{fus} that have been reported are 1627,[2] 1628,[3] 1627,[4] 1617,[5] and 1593 K.[6] The selected T_{fus} was obtained from measurements made on samples of BaF_2 contained in steel and molybdenum capsules. There were no indications of any reaction between the sample and container. Three of the lower values given above were determined from measurements on BaF_2 contained in either graphite[3,4] or tantalum[2] crucibles. It has now been established by mass spectroscopy[7,8] that the alkaline earth difluorides can be appreciably reduced by these materials near 1400 K. Thus, we prefer the higher value.

$\Delta_{fus}H°$ is obtained as the difference in the adopted functions for the liquid and crystal at T_{fus}.

Vaporization Data

T_{vap} is the calculated temperature at which $\Delta_r G° = 0$ for $BaF_2(l) \rightarrow BaF_2(g)$. $\Delta_{vap}H°$ is calculated from the difference in $\Delta_f H°(T_{vap})$ for the gas and liquid. Ruff and Le Boucher[9] derived $T_{vap} = 2533$ K and $\Delta_{vap}H° = 69.8\ kcal·mol^{-1}$ from an analysis of their vapor pressures (1960–2206 K).

Enthalpy of Formation

$\Delta_f H°(BaF_2, g, 298.15\ K) = -192.1 \pm 1.5\ kcal·mol^{-1}$ ($-803.7 \pm 6.3\ kJ·mol^{-1}$) is obtained from that of the crystal by addition of $\Delta_{sub}H° = 96.83 \pm 0.50\ kcal·mol^{-1}$. The selected $\Delta_{sub}H°$ is based on an analysis of six sets of vapor pressure data.[1-5] The results of our analysis are given below. A weighted value of these six results is adopted.

Source	Method	T/K	Data Points	$\Delta_{sub}H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	Drift cal·K^{-1}·mol^{-1}	$\Delta_f H°(298.15K)$ kcal·mol^{-1}

[a] $\Delta_{vap}H°$, 2[b], 4[c], and 3[d] points rejected due to failure of a statistical test.

Heat Capacity and Entropy

The bond length is taken from the high-temperature electron diffraction studies of Akishin and Spiridonov.[6] Although Akishin and Spiridonov[6] interpreted their results in terms of a linear configuration for BaF_2, recent electric-deflection experiments[7] and matrix isolation infrared studies[8,9] clearly indicate that BaF_2 is bent. Calder *et al.*[8] estimated the bond angle as 100° from the changes in the bond angles with mass of the central atom for other alkaline earth difluorides. Baikov[10] estimated the angle as 115°. We prefer a slightly lower value (95°) than these, since there are indications that other heavy metal halides have bond angles below 100°. For example, bond angles for PbF_2 and $PbCl_2$ have been reported as 90°[11] and 96 ± 3°,[12] respectively.

The symmetric (ν_1) and antisymmetric (ν_3) stretching frequencies are those observed by Calder *et al.*[8] in their study of infrared spectra of BaF_2 trapped in a krypton matrix. Other matrix frequencies in excellent agreement with the adopted ones have been reported by Snelson.[9] Further confirmation of the adopted ν_3 is provided by observations of Baikov.[13] He reported $\nu_3 = 415 \pm 7\ cm^{-1}$ which was observed in the infrared spectra of BaF_2 vapor at 1950 K. The bending frequency (ν_2) is that estimated by Calder *et al.*[8] This value is considerably less than that observed by Baikov[10] ($\nu_2 = 100\ cm^{-1}$). However, only the high frequency portion of this rather broad band was recorded. We have used our adopted frequencies in a valence bond calculation with the result k/(k δ/l²) = 11.8. This ratio of the stretching to bending force constants appears quite reasonable in comparison with those for other alkaline earth difluorides.[14] Also, our adopted frequencies give thermodynamic functions which show good compatibility with the vapor pressure data (see Enthalpy of Formation section).

The principal moments of inertia are: $I_A = 30.6016 \times 10^{-39}$, $I_B = 18.4604 \times 10^{-39}$, and $I_C = 12.1412 \times 10^{-39}\ g·cm^2$.

Enthalpy of Formation

The adopted $\Delta_f H°$(BaOH, g, 0 K) = −53.0 ± 7.0 kcal·mol^{-1} is based on an assessment of dissociation energies derived from Knudsen–cell mass–spectrometric measurements of Stafford and Berkowitz[1] and Newbury[2] and flame spectral work.[3–6]

Source	Reaction	No. Points	T/K	$\Delta_f H°$(298.15 K), kcal·mol^{-1} 3rd law	Drift cal·K^{-1}·mol^{-1}	$\Delta_f H°$(298.15 K) kcal·mol^{-1}	$D°_0$(Ba–OH) kcal·mol^{-1}

5	4	2	1570–1800	2.40 ± 2.39	7.3	−64.70	115.9

Reactions 1) BaO(cr) + BaO(g) + H_2O(g) → 2BaOH(g) + 0.5 O_2(g)
2) 2BaO(g) + H_2O(g) → 2BaOH(g) + O(g)
3) BaO(cr) + 0.5 H_2(g) = BaOH(g)
4) Ba(g) + H_2O(g) → BaOH(g) + H(g)

Ryabova and Gurvich[3] considered the reaction Ba(g) + H_2O(g) → BaOH(g) + H(g) to be dominant and derived $D°_0$ (as defined in the table above) = 111 ± 8 kcal·mol^{-1}. Sugden and Schofield[4] considered the reaction Ba(g) + 2H_2O(g) → Ba(OH)$_2$(g) + 2H(g) to be dominant. Cotton and Jenkins[5] found both the mono– and dihydroxide to be present in significant amounts in fuel–rich hydrogen–oxygen–nitrogen flames and derived $D°_0$ = 114 ± 5 kcal·mol^{-1}. Cotton and Jenkins[5] recalculated the work of Ryabova and Gurvich[3] and of Sugden and Schofield[4] considering both BaOH and Ba(OH)$_2$ to be present and obtained recalculated values of $D°_0$ = 110 and 114 kcal·mol^{-1}, respectively. Ryabova *et al.*[6] made further measurements, considered BaOH as dominant, and reported $D°_0$ = 109 ± 3 kcal·mol^{-1}. The $D°_0$ calculation from the 3rd law analysis of Cotton and Jenkins[5] data above, using auxiliary data,[7] is about 2 kcal·mol^{-1} higher than theirs. Applying this correction to the values from Ryabova and Gurvich[3] and Sugden and Schofield[4] as recalculated by Cotton and Jenkins,[5] gives 112 and 116 kcal·mol^{-1}, respectively. The value $D°_0$ = 109 ± 3 kcal·mol^{-1} given by Ryabova *et al.*[6] is an average of four calculations with two sets of molecular constants assumed for BaOH. This value, if recalculated with the present auxiliary data, would probably be higher.

The dissociation energies derived from flame spectra are higher, as a group, than those derived from the Knudsen cell mass spectrometric measurements. The ratio of $D°_0$ (monohydroxide)/$D°_0$(dihydroxide), where $D°_0$ of the dihydroxide is defined by the reaction Ba(OH)$_2$(g) → Ba(g) + 2 OH(g) and is 209.6 kcal·mol^{-1},[7] is approximately 0.53–0.55 for the flame spectral measurements and 0.50 for the average $D°_0$ = 105.3 kcal·mol^{-1} for the Knudsen–cell mass spectrometric measurements. The ratio for the barium mono– and difluoride[7] is 0.51, and the ratio for the other alkaline earth halides fall in the 0.40 to 0.51 range[7] with an average close to 0.46.[8] The similarity of the halides and hydroxides, particularly the fluorides, has been established.[1,9–11] $D°_0$ = 105.3 kcal·mol^{-1} is adopted from which is calculated $\Delta_f H°(0\ K)$ = −53.0 ± 7.0 kcal·mol^{-1}.

Heat Capacity and Entropy

The molecular configuration is assumed to be linear in accordance with the prediction of Walsh[12] and the evidence that gaseous alkali metal hydroxides are linear.[13–15] The ground state is assumed to be $^2\Sigma^+$ by analogy with BaF and BaCl.[7] The electronic levels are estimated from the observed band spectra[16–20] and the comparison with BaF and BaCl.[7]

The Ba–O bond distance is estimated to be slightly larger, 0.02 Å, than the Ba–F distance[7] after noting the close similarity in bond distance of the alkali metal fluorides and hydroxides. The O–H bond distance is that in water.[7] The Ba–O stretching frequency, 469 cm^{-1}, is estimated

Enthalpy of Formation

The ionization potential of BaOH(g) was deduced by Kelly and Padley[1] to be 5.25 ± 0.1 eV. These authors quantitatively examined the total positive ion concentrations produced from Ba aqueous salt additives in fuel rich, premixed $H_2 + O_2 + N_2$ flames. Using current JANAF auxiliary data,[2] we recalculate the ionization potential to be 5.36 eV.

Jensen[3] determined the enthalpy of reaction $\Delta_r H° = 6 \pm 10\ kcal \cdot mol^{-1}$ for $Ba(g) + OH(g) = BaOH^+(g) + e^-$ in atmospheric pressure $H_2 + O_2 + N_2$ flames using the microwave cavity resonance method. This value was calculated assuming a bent molecule for $BaOH^+$. The value is not significantly changed, within the uncertainty, by the change in the configuration. Using auxiliary data,[2] we derive an ionization potential of 4.83 eV, which is not in good agreement with the value derived from the data of Kelly and Padley.[1]

We adopt an ionization potential of 5.09 eV (117.38 $kcal \cdot mol^{-1}$) which is an average of the above two studies.[1, 3] This leads to $\Delta_f H°(0\ K) = 64.38\ kcal \cdot mol^{-1}$ and $\Delta_f H°(298.15\ K) = 64.75\ kcal \cdot mol^{-1}$ for $BaOH^+(g)$. We assign an uncertainty of ±15 $kcal \cdot mol^{-1}$.

For comparison, the ionization potential of BaF(g) is 4.83 eV[2] while that of Ba(g) is 5.21 eV.[4]
The average of these two values is very close to the ionization potential adopted for $BaOH^+$.

Heat Capacity and Entropy

The molecular configuration is assumed to be linear, since experimental evidence indicates that the gaseous alkali metal hydroxides are linear.[2, 5, 6, 7] In addition, Walsh[8] had predicted tha BAH molecules (H = hydrogen atom) with ten or less valence electrons ($BaOH^+$ has eight valence electrons) will be linear in their ground state. The molecule $BaOH^+$ is isoelectronic with CsOH.

The bond dissociation energy for $BaOH^+$ ($D_0° = 108.2\ kcal \cdot mol^{-1}$),[4, 2] for the process $BaOH^+(g) = Ba^+(g) + OH(g)$ is nearly the same as that for BaOH ($D_0° = 105.3\ kcal \cdot mol^{-1}$).[2] This suggests that the bonding in these two molecules is quite similar. Thus, the bond distances are assumed to be the same as those adopted for BaOH(g).[2] The vibrational frequencies are assumed to be similar to those adopted for BaOH(g).[2] The ground state quantum weight is assumed to be the same as that of CsOH(g).[2]

PREVIOUS: June 1976 (1 atm) CURRENT: June 1976 (1 bar)

$S°(298.15\ K) = [107.11 \pm 8.4]\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{,fus} = 681.15 \pm 1\ K$
$T_{trs} = 521 \pm 2\ K$ (β–α)

$\Delta_f H°(0\ K)$ = Unknown
$\Delta_f H°(298.15\ K) = [-946.30]\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 16.74 \pm 1.26\ kJ \cdot mol^{-1}$
$\Delta_{trs} H°$ = Unknown

Enthalpy of Formation

The adopted $\Delta_f H°(298.15\ K) = -226.17 \pm 1.5\ kcal \cdot mol^{-1}$ is obtained from the enthalpy of formation of the liquid[1] minus the enthalpy of fusion and the enthalpy difference of the liquid and the crystal between the melting point and 298.15 K. Using auxiliary data,[1] our 2nd and 3rd law analysis of the dissociation pressure equation of Kondakov *et al.*[2] for the reaction Ba(OH)$_2$(cr) = BaO(cr) + H$_2$O(g) is given below.

	$\Delta_r H°(298.15\ K)$, $kcal^{-1} \cdot mol^{-1}$		Drift	$\Delta_f H°(298.15\ K)$
T/K	2nd law	3rd law	$cal \cdot K^{-1} \cdot mol^{-1}$	$kcal \cdot mol^{-1}$
559–682	46.4	38.04 ± 1.63	−13.5 ± 0.2	−226.84 ± 2

While this is in good agreement with the adopted value, there is an inconsistency in the measurements of Kondakov *et al.*[2] for the crystal and the liquid and the adopted enthalpy of fusion. The liquid state dissociation pressures are in good agreement with other measurements (see the liquid table)[1] and are judged more reliable than the solid state measurements. The adopted value for the alpha crystal is also in good agreement with −225.8 kcal from another recent evaluation.[4]

Heat Capacity and Entropy

The heat capacities at 298.15 K and above are derived from the drop–ice–calorimeter enthalpy measurements of Powers and Blalock,[3] 425–681 K) combined with a graphical comparison of the heat capacities of Mg(OH)$_2$(cr) and Ca(OH)$_2$(cr)[1] From the information referenced in the Transition Data Section below, it is concluded tha the α–form is maintained on cooling to 273.15 K. This JANAF Table is a single–phase alpha–crystal table.

The adopted entropy, $S°(298.15\ K) = [25.6 \pm 2]\ cal \cdot K^{-1} \cdot mol^{-1}$, is calculated from Kelley's additive entropy constants for cations and anions.[5]

Fusion Data

Seward[6] determined a melting point of 408 ± 1°C and a cryoscopic enthalpy of fusion of 3400 ± 100 cal·mol^{-1}. Powers and Blalock[3] chose a melting point of 395°C where they found $\Delta_{fus}H° = 24$ cal/g (4113 $cal \cdot mol^{-1}$) by drop calorimetry. However, their enthalpy measurements show a possible melting range of 395 to 421°C. (At the adopted temperature of melting, 408°C, our smoothing of Powers and Blalock's experimental enthalpies[3] leads to $\Delta_{fus}H° = 4051\ cal \cdot mol^{-1}$). Kondakov *et al.* observed barium hydroxide to melt at 682 K (ca. 409°C) while investigating the dissociation pressures of the crystal and liquid states. Michaud[7,8] determined a melting point of 409 ± 1°C and a cryoscopic enthalpy of fusion of 3720 ± 200 $cal \cdot mol^{-1}$.[8] From a consideration of all of these data, a melting point of 681.15 ± 1 K (408 ± 1°C) and a enthalpy of fusion of 4000 ± 300 $cal \cdot mol^{-1}$ are adopted.

Transition Data

Michaud has observed a β to α crystal transition, on heating anhydrous barium dihydroxide, at 250°C[7] and at 246°C[8] by both thermal and dilatometric techniques. In the absence of water vapor, the high temperature α–form is maintained on cooling to room temperature.[7] This "metastable" state has been confirmed by others.[9,10] This present JANAF Table considers only the α–form. A transition temperature of 521 ± 2 K (248 ± 2°C) is adopted.

$S°(298.15\ K) = [123.357]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 681.15 \pm 1\ K$

$\Delta_f H°(298.15\ K) = [-934.123]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 16.74 \pm 1.26\ kJ·mol^{-1}$

Enthalpy of Formation

The adopted $\Delta_f H°(298.15\ K) = -223.26 \pm 1.0\ kcal·mol^{-1}$ is the average of values derived from the 3rd law analysis of dissociation pressure measurements of Tamaru and Shiomi[1] and of Kondakov *et al.*[2] Auxiliary data used in the analysis are from the JANAF Thermochemical Tables.[3] Johnston[4] has also determined pressures for the dissociation reaction $Ba(OH)_2(l) = BaO(cr) + H_2O(g)$.

Source	No. of Points	T/K	$\Delta_f H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	Drift cal·K^{-1}·mol^{-1}	$\Delta_f H°(298.15)$ kcal·mol^{-1}
Tamaru and Shiomi[1]	7	788–1018	32.1	34.56 ± 0.48	2.8 ± 0.5	−223.35 ± 1
Kondakov *et al.*[2]	Equation	682–993	34.0	34.37 ± 0.21	0.4	−223.17 ± 0.7
Johnston[4]	11	918–1263	34.4	33.86 ± 0.38	−0.5 ± 0.5	−222.66 ± 0.9

The enthalpy of formation derived from Johnston's measurements is in good agreement with the adopted value but is not averaged in because, as indicated by Kondakov *et al.*,[2] the measurements are believed less accurate.

Heat Capacity and Entropy

$C_p°$ is based on the enthalpy measurements of Powers and Blalock[5] and is assumed constant at 33.7 cal·K^{-1}·mol^{-1} over the range of 450 to 1600 K. A glass transition is assumed at 450 K below which $C_p°$ is that of the alpha crystal. The entropy at 298.15 K is derived from the value adopted for the alpha crystal.

Decomposition Data

T_{dcm} is calculated as the temperature at which $\Delta_r G° = 0$ for the reaction $Ba(OH)_2(l) = BaO(cr) + H_2O(g)$.

Enthalpy of Formation

The adopted $\Delta_f H°(298.15\ K) = -149.75 \pm 9.0\ kcal \cdot mol^{-1}$ is derived from the Knudsen–cell mass–spectrometric equilibrium study of Newbury.[1] Tabulated below are the results of a 2nd and 3rd law analysis of this study,[1] the Knudsen–cell mass–spectrometric work of Stafford and Berkowitz,[2] and the flame–spectral work of Cotton and Jenkins.[3]

Source	Rxn No.	No. of Points	T/K	$\Delta_f H°(298.15\ K)$, kcal·mol^{-1} 2nd law	3rd law	Drift cal·K^{-1}·mol^{-1}	$\Delta_f H°(298.15\ K)$ kcal·mol^{-1}	$D_0°$ kcal·mol^{-1}

Cotton and Jenkin[3]	B	2	1570–1800	8.1	23.04 ± 2.98	8.8 ± 0.0	−153.96 ± 4.0	213.8

Reactions: A) $BaO(cr) + H_2O(g) = Ba(OH)_2(g)$ B) $Ba(g) + 2H_2O(g) = Ba(OH)_2(g) + 2H(g)$

a. Two points rejected by a statistical test.

b. $D_0°$ is the dissociation energy for the reaction $Ba(OH)_2(g) = Ba(g) + 2OH(g)$.

In addition to the three investigations above, dissociation energies ($D_0°$ as defined in the table above) have been derived from flame spectra by Ryabova and Gurvich[5] and by Sugden and Schofield.[6] Ryabova and Gurvich[5] believed the dominant reaction to be $Ba(g) + H_2O(g) = BaOH(g) + H(g)$, but they also considered the possibility that the reaction $Ba(g) + 2H_2O(g) = Ba(OH) + 2H(g)$ was dominant and derived $D_0° = 205 \pm 20\ kcal \cdot mol^{-1}$. Sugden and Schofield[6] considered the dihydroxide to be the domiant product and derived $D_0° = 229 \pm 12\ kcal \cdot mol^{-1}$. Cotton and jenkins[3] found both BaOH and $Ba(OH)_2$ to be present and obtained recalculated $D_0°$ values of 208 and 212 $kcal \cdot mol^{-1}$, respectively.

The 3rd law analysis of the data of Cotton and Jenkins[3] above combined with current JANAF Thermochemical Table data[4] leads to $D_0° = 213.8\ kcal \cdot mol^{-1}$ which is 0.8 $kcal \cdot mol^{-1}$ higher than the 213 $kcal \cdot mol^{-1}$ derived by Cotton and Jenkins.[3] Applying this difference to the values of Ryabova and Gurvich[5] and of Sugden and Schofield[6] as recalculated by Cotton and Jenkins[3] gives $D_0° = 208.8$ and 212.8 $kcal \cdot mol^{-1}$, respectively.

The average of the dissociation energies from the flame–spectral measurements (208.8, 212.8, and 213.8) and the dissociation energy from the Knudsen–cell mass–spectrometric work of Stafford and Berkowitz (203.3) is 209.7 $kcal \cdot mol^{-1}$ which happens to be in agreement with the 209.6 $kcal \cdot mol^{-1}$ calculated from Newbury's data.

$\Delta_f H°(298.15\ K) = -149.75 \pm 9.0\ kcal \cdot mol^{-1}$ is adopted because of the excellent agreement in the 2nd and 3rd law enthalpies of reaction from Newbury's data[1] and because of the larger uncertainty associated with dissociation energies derived from flame spectra.

The enthalpy of dissociation listed by Jackson[9] leads to $\Delta_f H°(298.15\ K) = -151.22\ kcal \cdot mol^{-1}$. Another recent compilation[10] lists $\Delta_f H°(298.15\ K) = -140\ kcal \cdot mol^{-1}$.

Heat Capacity and Entropy

The analogy between gaseous mono– and dihydroxides and gaseous mono– and dihalides, particularly the mono– and difluorides, has been recognized.[2,7–9] The O–Ba–O bond angle is assumed to be the same as the F–Ba–F bond angle;[4] the Ba–O–H bond angle is considered to be linear as in BaOH.[4] The Ba–O bond distance is estimated to slightly larger, 0.02 Å, than the Ba–F distance in BaF_2[4] after noting the close similarity in the bond distance of the alkale metal fluorides and hydroxides. The O–H bond distance is taken to be the same as in water.[4]

The vibrational frequencies are assumed to be the same as in BaF_2[4] (O–Ba–O symmetrical and asymmetrical stretch, and bend) and as in BaOH[4] (O–H stretch and Ba–O–H bend). The principal moments of inertial are: $I_A = 29.8004 \times 10^{-39}$, $I_B = 17.7971 \times 10^{-39}$, and $I_C = 12.0033 \times 10^{-39}\ g \cdot cm^2$.

$S°(298.15\ K) = 278.74 \pm 0.21\ J·K^{-1}·mol^{-1}$

$\Delta_f H°(0\ K) = -39.29 \pm 84\ kJ·mol^{-1}$
$\Delta_f H°(298.15\ K) = -42.42 \pm 84\ kJ·mol^{-1}$

Electronic Levels and Quantum Weights		
State	ϵ_i, cm^{-1}	g_i
$X[^2\Sigma^+]$	0	2
$C[^2\Pi]$	17816.3	2
	18568.8	2
$D[^2\Sigma^+]$	25764.4	2
$E[^2\Sigma^+]$	26753.3	2

$\omega_e = 152.2\ cm^{-1}$ $\omega_e x_e = 0.29\ cm^{-1}$ $\sigma = 1$
$B_e = [0.0250]\ cm^{-1}$ $\alpha_e = [0.000059]\ cm^{-1}$ $r_e = [3.20]$ Å

Enthalpy of Formation

The adopted $\Delta_f H°(0\ K) = -9.39 \pm 20\ kcal·mol^{-1}$ is calculated from $D_0° = 3.37$ eV (77.7 $kcal·mol^{-1}$) calculated by a linear Birge–Sponer extrapolation of $\omega_e x_e$ data[1] with a correction for the ionic character of the molecule as described by Hildenbrand.[2] Other values, in $kcal·mol^{-1}$, are 55[3] predicted from a correlation of binding energies of Group II and Group III diatomic hydrides and halides, 71.7[4] as a lower bound from a consideration of ionic bonding forces and 66[5] derived as a lower bound from a consideration of energy conservation and measured reaction threshold relative kinetic energy from crossed molecular beam experiments. $D_0° = 77.7\ kcal·mol^{-1}$ is adopted because the ratio of $D_0°(BaI)/\Delta_{at}H°(BaI_2) = 0.47$ which is nearly the same as the ratio of 0.46 found for a series of mono- and difluorides[6] and for other alkaline earth halides systems.[8]

$\Delta_f H°(298.15\ K) = -10.14 \pm 20\ kcal·mol^{-1}$ is calculated from the adopted $\Delta_f H°(0\ K) = -9.39 \pm 20\ kcal·mol^{-1}$.

Heat Capacity and Entropy

The ground state vibrational constants are from the compilation of Rosen.[1] The adopted value of $r_e = 3.20$ Å was estimated by Margrave[3] and is also the bond distance in $BaI_2(g)$.[7] B_e is calculated from the adopted r_e; α_e is calculated assuming a Morse potential function.

The electronic levels and their probable designation are those given by Rosen.[1]

$S°(298.15\ K) = 165.14 \pm 0.4\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 984 \pm 2\ K$

$\Delta_f H°(0\ K) = -604.5 \pm 3.3\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -605.4 \pm 3.3\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = 26.53 \pm 0.54\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Ehrlich, Peik, and Koch[1] derived $\Delta_f H°(BaI_2, cr, 298.15\ K) = -144.7 \pm 0.4\ kcal \cdot mol^{-1}$ from enthalpy of solution measurements of Ba(cr) and BaI_2(cr) in 0.1 N HI. An auxiliary HI enthalpy of solution value, $-13.22\ kcal \cdot mol^{-1}$, calculated from data in reference[2] was used in the derivation. This auxiliary value will be changed by incorporation of the accepted CODATA key value of $\Delta_f H°(I^-, aq, 298.15\ K) = -13.60\ kcal \cdot mol^{-1}$[3] in the $\Delta_f H°$(HI, aq, 298.15 K) table, so that the above derived enthalpy of formation of BaI_2(cr) will be approximately $-145.1\ kcal \cdot mol^{-1}$.

Combining $\Delta_f H°(Ba^{+2}, aq, 298.15\ K) = -128.5\ kcal \cdot mol^{-1}$, selected by Parker,[4] with the CODATA value for $I^-(aq)$[3] gives $\Delta_f H°(BaI_2, aq, 298.15\ K) = -155.7\ kcal \cdot mol^{-1}$. Further combination with the enthalpy of solution, $-10.98\ kcal \cdot mol^{-1}$,[5, 11] gives $\Delta_f H°(BaI_2, cr, 298.15\ K) = -144.7\ kcal \cdot mol^{-1}$. This enthalpy of solution value was based on several sets of data, one of which was that of Ehrlich *et al.*[1,11]

We adopt $-144.7 \pm 0.8\ kcal \cdot mol^{-1}$ ($-605.425 \pm 3.347\ kJ \cdot mol^{-1}$) because of the correlation of $\Delta_f H°(Ba^{+2}, aq, 298.15\ K)$ with the evaluation of data for several barium compounds.[4] See also the updated discussion in the enthalpy of formation section for BaO(cr).[12]

Heat Capacity and Entropy

$C_p°$ (13.08–300.17 K) has been measured by Paukov, Khriplovich, and Smirnova.[6] Our T^3 extrapolation agrees with their $S°(13) = 0.619\ cal \cdot K^{-1} \cdot mol^{-1}$ and $H°(13\ K) - H°(0\ K) = 6.01\ cal \cdot K^{-1} \cdot mol^{-1}$, and our smoothing and integration of their $C_p°$ data agrees with their $S°(298.15\ K) = 39.47 \pm 0.1\ cal \cdot K^{-1} \cdot mol^{-1}$ which is adopted.

The low-temperature heat capacities join smoothly with a linear extrapolation from $C_p°(298.15\ K) = 18.52\ cal \cdot K^{-1} \cdot mol^{-1}$ to Dworkin and Bredig's reported $C_p°$ of 21.8 $cal \cdot K^{-1} \cdot mol^{-1}$ at the adopted T_{fus} of 984 K.[7] This gives $H°(984\ K) - H°(298.15\ K) = 13.83\ kcal \cdot mol^{-1}$, in fair agreement with Dworkin and Bredig's drop calorimeter value of $13.9\ kcal \cdot mol^{-1}$.[7]

Fusion Data

Dworkin and Bredit[7] report $\Delta_{fus} H° = 6.34\ kcal \cdot mol^{-1}$ (±2%) at T_{fus} of 984 K from drop calorimetry; Emons and Loeffelholz[8] found 6.050 $kcal \cdot mol^{-1}$ (±5%) at a reported , T_{fus} of 981 K by high temperature cryoscopy. Hutchison[9] determined T_{fus} to be 983 K, while Kubaschewski *et al.*[10] listed 985 K. We adopt $\Delta_{fus} H° = 6.34 \pm 0.13\ kcal \cdot mol^{-1}$ and $T_{fus} = 984 \pm 2$ K.

Sublimation Data

$\Delta_{sub} H°(298.15\ K)$ is calculated as the difference between the enthalpies of formation of the ideal gas and the crystal at 298.15 K.

PREVIOUS: CURRENT: June 1974

$S°(298.15\ K) = [183.669]\ J·K^{-1}·mol^{-1}$
$T_{fus} = 984 \pm 2\ K$

$\Delta_f H°(298.15\ K) = [-585.884]\ kJ·mol^{-1}$
$\Delta_{fus} H° = 26.53 \pm 0.54\ kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°(BaI_2, l, 298.15\ K)$ is calculated from that of the crystal by adding $\Delta_{fus} H°$ and the difference in ethalpy, $H°(984\ K) - H°(298.15\ K)$, between the crystal and liquid.

Heat Capacity and Entropy

The liquid heat capacity near the melting point, 27.0 $cal·K^{-1}·mol^{-1}$, was determined by Dworkin and Bredig[1] from drop calorimetric measurements. This value is adopted and assumed constant over a 700–2800 K range. A glass transition is assumed at 700 K below which the heat capacity is that of the crystal.

$S°(298.15\ K)$ is calculated in a manner similar to that used for the enthalpy of formation.

Vaporization Data

The temperature at which $\Delta_r G° = 0$ for the reaction $BaI_2(l) = BaI_2(g)$ is the adopted T_{vap}. Peterson and Hutchison[2] have extrapolated Knudsen effusion cell measurements in the 1154–1301 K range to obtain a normal boiling point (1 atm) of 2300 K.

$\Delta_{vap} H°(T_{vap})$ is the calculated difference between the enthalpies of formation of the ideal gas and the liquid at T_{vap}. Refer to the ideal gas table for details.

Ground State Quantum Weight: [1] $\sigma = 2$
Point Group: C_{2v}
Bond Distance: Ba–I = 3.20 ± 0.03 Å
Bond Angle: I–Ba–I = [170]°
Product of Moments of Inertia: $I_A I_B I_C = 2.117174 \times 10^{-112}\ g^3·cm^6$

Enthalpy of Formation

Winchell[1] has reported ΔH, ΔG, and ΔS for the vaporization of BaI_2(l) at 1150 K derived from a mass spectrometric Knudsen effusion cell investigation (28 unpublished points in the range of 1019–1278 K). The spectra showed no evidence of BaI_2 polymers; also it was consluded that BaI_2(l) = BaI_2(g) is the important vaporization. Peterson and Hutchison[2,3] used a weight loss Knudsen effusion technique to observe vapor presured at 18 temperatures in the range of 1154–1301 K. Their enthalpy of vaporization, 53.6 ± 1.3 kcal·mol^{-1}, is in good agreement with Winchell's value, 54 ± 4 kcal·mol^{-1}.

Source	No. of Points	T/K	$\Delta_r H°$(298.15 K), kcal·mol^{-1} 2nd law	3rd law	Drift cal·K^{-1}·mol^{-1}
Winchell[1]	3[a]	1019–1278	62.16	68.07	5.1
Peterson and Hutchison[2]	18[b]	1154–1301	64.35 ±1.5	67.61 ±0.5	2.6 ±1.2

[a]ΔG calculated at 1019 K and 1278 K from ΔH, ΔG, and ΔS values given at 1150 K to permit use of 2nd law.
[b]one point rejected by statistical tests.

We select $\Delta_{vap}H°(298.15\ K) = 67.6 \pm 3$ kcal·mol^{-1} and combine this with $\Delta_f H°$(I, 298.15 K) = −140.029 ± 0.9 kcal·mol^{-1} to give the adopted $\Delta_f H°$(g, 298.15 K) = −72.4 ± 4 kcal·mol^{-1}.

Heat Capacity and Entropy

The bond distance, as determined from an electron diffraction study, is taken from the work of Akishin *et al.*[4] who also judged the bond angle to be 180 ± 20°. The later electric deflection study of Buechler *et al.*[5] showed that all of the barium dihalide molecules are bent. Noting the trend in the magnitude of the bond angle in the alkaline earth–halide series, we have assumed a bond angle of 170°. The principal moments of inertia are: $I_A = 429.4543 \times 10^{-39}$, $I_B = 428.3033 \times 10^{-39}$, and $I_C = 1.1510 \times 10^{-39}$ g cm^2.

In estimating the vibrational frequencies, the stretching force constants for gaseous BaF, BaF_2, BaCl, and $BaCl_2$ are calculated from their vibrational frequencies,[6] using the valence force model. The trend in the ratio k(monohalide)/k_1(dihalide) indicates that k(BaI)/k_1(BaI_2) = 1 is a reasonable approximation, an approximation used by Brewer *et al.*[7] The stretching force constant for BaI(g) is calculated from the ground state vibrational frequency given by Rosen.[8] The bending force constant is assumed to be 0.01 times the stretching force constant.[7] The adopted vibrational frequencies are calculated from these estimated force constants. Other estimates for ν_1, ν_2, and ν_3 where a linear molecule was assumed, are 109, 26, 184[7] and 106, 37, 178.[9]

We assign an uncertainty of ±2 cal·K^{-1}·mol^{-1} to the entropy to allow for error in the estimation of bond angle and of the vibrational frequencies.

PREVIOUS: June 1974 (1 atm) CURRENT: June 1974 (1 bar)

$S°(298.15\ K) = 72.069 \pm 0.38\ J \cdot K^{-1} \cdot mol^{-1}$
$T_{fus} = 2286 \pm 15\ K$

$\Delta_f H°(0\ K) = -546.8 \pm 2.1\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -548.1 \pm 2.1\ kJ \cdot mol^{-1}$
$\Delta_{fus} H° = [59]\ kJ \cdot mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is rounded from -130.98 ± 0.47 kcal·mol^{-1} derived by Fitzgibbon *et al.*[1] from calorimetric reactions of HCl(aq) with Ba(cr) and BaO(cr). Combination of their two reactions yields $\Delta_f H°(298.15\ K) = -62.66 \pm 0.47$ kcal·mol^{-1} for Ba(cr) + H_2O(l) → BaO(cr) + H_2(g). Although the resulting $\Delta_f H°$ is 1.3 kcal·mol^{-1} less negative than that of NBS Technical Note 270–6,[2] it confirms Parker's selection[2] of key values for BaO and $BaCl_2$ from calorimetry involving aqueous HCl[3–5] instead of discrepant values derived from other reactions.[6–8] Earlier HCl calorimetry gave $\Delta_f H°$(BaO, cr) = -132.0[3,2] and -132.1 kcal·mol^{-1}.[4,5] The new value[1] is preferred since both reactions were run in the same calorimeter on samples that were well characterized. The latter is particulaly important since impurities were a major problem in studies of BaO[3,4,9–14] and Ba.[2,5–7]

Direct measurements of $\Delta_c H$ of Ba(cr) by Mah[6] gave -139.06 ± 0.7 kcal·mol^{-1}. Combustion studies of Fitzgibbon *et al.*[1] suggest that the negative bias of 8 kcal·mol^{-1} was due to partial dissolution of the crucible lining (MgO) in molten BaO formed in the combustion. Dissolution was eliminated in combustions on sintered MgO disks, but large amounts of BaO_2 were formed both in this case and with the use of BaO crucibles.[1] This led the authors[1] to dismiss combustion calorimetry in favor of solution calorimetry. Parker[2] noted earlier that the combustion result was incompatible with data for $BaCl_2$(aq), $Ba(OH)_2$(aq and cr), BaO_2(cr) and $BaCO_3$(cr); also a similar discrepancy existed for SrO(cr). We find that the combustion value is incompatible with equilibrium data[19] for $BaCl_2$(l and g).

$\Delta_f H°(BaCl_2, cr)$ and $\Delta_f H°(Ba^{2+}, aq)$ deserve an updated discussion. We combine $\Delta_f H° = -127.95 \pm 0.41$ kcal·mol^{-1} [1] for Ba(cr) + 2HCl(54.3 H_2O) = H_2(g) + $BaCl_2$ [in 149.9 HCl (55.0 H_2O)] with $\Delta_f H°$(HCl, 54.3 H_2O) = -39.52 ± 0.02 kcal·mol^{-1} [16] and $\Delta_{sol} H° = -2.09 \pm 0.2$ kcal·mol^{-1} [17,18,2] for $BaCl_2$(cr) in HCl(55 H_2O) to give $\Delta_f H°(BaCl_2, cr) = -204.9 \pm 0.5$ kcal·mol^{-1}. This confirms the JANAF[19] $\Delta_f H°(BaCl_2)$ of -205.2 kcal·mol^{-1} based on the selection of Parker;[2] the alternative uncertainty of ± 0.6 kcal·mol^{-1} should now be used instead of ± 3 kcal·mol^{-1}.[19] The new $\Delta_f H°$ for $BaCl_2$[1] yields $\Delta_f H°(Ba^{2+}, aq) = -128.0 \pm 0.6$ kcal·mol^{-1}, assuming $\Delta_{sol} H°(BaCl_2, cr) = -3.0 \pm 0.2$ kcal·mol^{-1} (many references) and $\Delta_f H°(Cl^-, aq) = -39.933 \pm 0.021$ kcal·mol^{-1}.[16] This is consistent with Parker's selection of $\Delta_f H°(Ba^{2+}, aq) = -128.5$ kcal·mol^{-1}.[2]

Heat Capacity and Entropy

$C_p°$ is based on data (1.4–310 K) of Gmelin[12] who reported smoothed values only in the range 4 to 300 K. Based on Gmelin's graphs, we have corrected several typographical errors and resmoothed $C_p°$ above 240 K where the scatter increases rapidly. The entropy is obtained by integration of our adopted $C_p°$ using $S° = 0.0015$ cal·K^{-1}·mol^{-1} at 4 K. The value $S° = 15.75 \pm 0.02$ cal·K^{-1}·mol^{-1} reported by Gmelin[12] corresponds to neither 273.15 K nor 298.15 K and must be erroneous. $C_p°$ data (56–299 K) of Anderson[13] differ by $\pm 1.6\%$ but average about 1.0% higher from 150 to 260 K.

$C_p°$ above 300 K is from constrained fitting of enthalpy data (391–1299 K) of Lander.[14] This calorimetry is subject to bias from a calibration based on Pt and from impurities in the two samples. Information is insufficient to assess the bias due to minor changes in the enthalpy of Pt.[15] We apply crude corrections to the observed enthalpies for 27 mole % SrO in one sample and for about 2.8 mole % SiO_2 in the other sample. Deviations from the adopted curve are $\pm 0.9\%$ (first sample) and $\pm 1.0\%$ (second sample) except for -2.0% at 421 K.

Fusion Data

Refer to the liquid table for details.

Sublimation Data

$\Delta_{sub} H°$ is calculated as the difference in $\Delta_f H°$ between gas and crystal.

Continued on page 359

$S°(298.15\ K)$ = [96.553] $J·K^{-1}·mol^{-1}$
T_{fus} = 2286 ± 15 K

$\Delta_f H°(298.15\ K)$ = [−491.627] $kJ·mol^{-1}$
$\Delta_{fus}H°$ = [59] $kJ·mol^{-1}$

Enthalpy of Formation

$\Delta_f H°$ is calculated from that of the crystal by addition of $\Delta_{fus}H°$ and the difference in enthalpy, $H°(2286\ K)-H°(298.15\ K)$, between crystal and liquid.

Heat Capacity and Entropy

$C_p°$ of the liquid is estimated as 8 $cal·K^{-1}$ g-$atom^{-1}$ by comparison with other oxides. $C_p°$ is taken from the crystal in the range 298.15 K up to the glass transition assumed at 1600 K. $S°$ is calculated in a manner analogous to that used for $\Delta_f H°$.

Fusion Data

Foex[1] obtained T_{fus} = 2010°C from a solar-furnace study using BaO as its own container. We adopt this result but increase it by 3° for conversion to IPTS-68. Foex showed that the much lower value (1918°C) of Schumacher[2,3] probably resulted from contamination by WO_3 from tungsten supports of the sample. $\Delta_{fus}H°$ is estimated such that $\Delta_{fus}S°$ is 6 $cal·K^{-1}·mol^{-1}$.

Vaporization Data

Unlike the other alkaline-earth oxides, BaO(cr) vaporizes mainly to BaO(g) with traces of Ba_2O_2 and Ba_2O. Mass-spectrometric studies[4] suggest that decomposition to Ba(g) and O(g) is not a major contributor even though the observed intensities of Ba^+ are almost comparable with those of BaO^+. T_{vap} is the calculated temperature at which $\Delta_f G° = 0$ for BaO(l) = BaO(g); $\Delta_{vap}H°$ is the corresponding difference in $\Delta_f H°$.

Enthalpy of Formation

We adopt $D_0° = 131.0 \pm 2$ kcal·mol^{-1} and $\Delta_f H°(298.15\ K) = -29.6 \pm 2$ kcal·mol^{-1} based on equilibria and vaporization data analyzed below. The results are in excellent agreement, even though δS varies widely. The dissociation energy is confirmed also by values of 132 ± 5(electron impact),[17] ≥ 131.4 (crossed-beam chemiluminescence),[18] and 131 kcal·mol^{-1} (flame study, 1973).[7] We have adjusted the latter value to make it roughly consistent with our Gibbs energy functions. Less reliable data were reviewed by Schofield.[19] Our analysis supports the conclusions of Brewer and Rosenblatt.[20]

Heat Capacity and Entropy

Electronic levels (T_e) and vibrational–rotational constants of the observed states are from Field[1] and Rosen.[2] The long-sought $a^3\Pi$ and $A'^1\Pi$ states of CaO, SrO and BaO were characterized by Field[1] using a new method for assignment of perturbations. This study resolved the long-standing controversy over low-lying electronic levels and confirmed[1] that $X^1\Sigma^+$is the ground state.[4] We estimate the other potentially low-lying state ($^3\Sigma^+$) at 14000 cm^{-1} by assuming that it lies 3000 ± 2500 cm^{-1} [1,5] below the isoconfigurational A state. Other predicted states and their vibrational–rotational constants are estimated in isoconfigurational groups by comaprison with BeO, MgO, CaO and SrO.[5] Comparisons are facilitated by listing the states in the isoconfigurational order of MgO.[5] Our thermodynamic functions correspond to an "effective" ground state with $g = 1$ instead of $g = 6$.[10,19] Our functions are calculated using first-order anharmonic corrections to Q_r^i and Q_v^i in the partition function $Q = Q_t \Sigma Q_r^i Q_v^i g_i \exp(-c_2\epsilon_i/T)$.

$S°(298.15\ K) = 78.4 \pm 1.3\ J \cdot K^{-1} \cdot mol^{-1}$

$\Delta_f H°(0\ K) = -462.7 \pm 2.1\ kJ \cdot mol^{-1}$
$\Delta_f H°(298.15\ K) = -463.6 \pm 2.1\ kJ \cdot mol^{-1}$

Enthalpy of Formation

Sabatier[1] measured the enthalpy of solution of BaS in hydrochloric acid solution as $\Delta_r H°(284\ K) = -27.0 \pm 1.0\ kcal \cdot mol^{-1}$ for $BaS(cr) + 2HCl(100\ H_2O, aq) \rightarrow BaCl_2(100\ H_2O, aq) + H_2S(aq)$. We derive $\Delta_f H°(298.15\ K) = -111.0 \pm 2.0\ kcal \cdot mol^{-1}$ based on the following auxiliary data: $\Delta_f H°(HCl \cdot 100\ H_2O, aq, 298.15\ K) = -39.657\ kcal \cdot mol^{-1}$,[2] $\Delta_f H°(H_2S, aq, 298.15\ K) = -9.5\ kcal \cdot mol^{-1}$,[2] and $\Delta_f H°(BaCl_2 \cdot 100\ H_2O, aq, 298.15\ K) = -207.803\ kcal \cdot mol^{-1}$.[3] Mourlot[4] also measured the enthalpy of solution of BaS in hydrochloric acid solution as $\Delta_r H° = -27.35 \pm 1.0\ kcal \cdot mol^{-1}$ from which we calculate $\Delta_f H°(298.15\ K) = -110.6 \pm 2\ kcal \cdot mol^{-1}$ using the same auxiliary data. The uncertainties quoted reflect the correction to 298.15 K and the ambiguity of the exact solution composition.

Our analyses of equilibrium studies of Okuno,[5] Culver and Hamdorf,[6] Nikonov,[7] Schenck and Hammerschmidt,[8] and Colin *et al.*,[9] are listed below. The calculated 3rd law $\Delta_f H°(298.15\ K)$ may have an uncertainty of 0.5 $kcal \cdot mol^{-1}$ since the JANAF Gibbs energy functions are partially based on the estimated $C_p°$ data (above 300 K). The enthalpy of formation of BaS(cr) derived from equilibrium studies is in good agreement with that derived from enthalpy of solution studies.[1,4] We discount the studies of Nikonov[7] and of Colin *et al.*[9] More information is given in the SrS(cr) table.[10]

A weighted average, $\Delta_f H°(BaS, cr, 298.15\ K) = -110.8 \pm 0.5\ kcal \cdot mol^{-1}$, is adopted in the tabulation.

E) $Ba(g) + 2S_2(g) = BaS(cr) + 3S(g)$

Heat Capacity and Entropy

King and Weller[11] measured the low temperature heat capacities from 54–296 K. Their smooth values are adopted in the tabulation. The entropy, $S°(298.15\ K) = 18.7 \pm 0.2\ cal \cdot K^{-1} \cdot mol^{-1}$, is based on $S°(51\ K) = 2.60\ cal \cdot K^{-1} \cdot mol^{-1}$ as extrapolated by King and Weller using Debye and Einstein functions ($\theta_D = 159$, $\theta_E = 267$). The $C_p°$ values above 300 K are estimated by graphical extrapolation combined with method B of Kubaschewski *et al.*[12]

Fusion Data

Literature melting data for BaS(cr) are not available. It has been reported[13,14] that BaS melts above 2500 K but this value must be looked upon as a lower limit.

Enthalpy of Formation

The adopted value of the enthalpy of formation, $\Delta_f H°(BaS, g, 298.15\ K) = 9.03 \pm 3.0\ kcal·mol^{-1}$, is based on the Knudsen mass-spectrometric study of Colin *et al.*[3] Our reanalysis of their ion intensity data is given below. Although the large drift would suggest a larger uncertainty in the derived quantities ($\Delta_f H°$, $D_0°$), our experience with related work on other alkaline earth sulfides and oxides by the same authors indicates that results derived from a 3rd law analysis are preferred. Our value of the enthalpy of formation is intermediate between $\Delta_f H°(298.15\ K) = 7.3 \pm 5\ kcal·mol^{-1}$ obtained by Mills[6] (using different Gibbs energy functions) in a recent critical compilation and $\Delta_f H°(298.15\ K) = 12.0\ kcal·mol^{-1}$ preferred by NBS.[7] Using auxiliary JANAF data,[8] and the recommended value for $D_0°$ (S_2, g) = 100.69 ± 0.01 $kcal·mol^{-1}$,[8] we calculate $D_0°$ (BaS, g) = 99.3 ± 3 $kcal·mol^{-1}$. A linear Birge–Sponer extrapolation of the $X^1\Sigma^+$ ground state based on the data of Barrow *et al.*,[1] after an ionic correction due to Hildenbrand,[4] yields the dissociation energy of 99.8 $kcal·mol^{-1}$ for the products $Ba(^1S) + S(^1D)$. The $X^1\Sigma^+$ ground state cannot dissociate to ground state atoms. If the dissociation products are instead $Ba(^3D) + S(^3P)$, analogous to the work of Field *et al.*[5] on BaO, the dissociation energy becomes $D_0° = 100.4\ kcal·mol^{-1}$. Both of these values are uncertain due to the very long vibrational extrapolation.

[a]Reaction: A) $Ba(g) + S_2(g) = BaS(g) + S(g)$

Heat Capacity and Entropy

Electronic levels (T_{oo}) and vibrational–rotational constants of the observed states are from the optical study of Barrow *et al.*[1] and the microwave work of Tiemann *et al.*[2] Other low-lying electronic states and their vibrational–rotational constants are estimated in isoconfigurational groups by analogy with BaO[8] and from trends observed in the known states of the other alkaline-earth oxides and sulfides. Thermodynamic functions are calculated using first-order anharmonic corrections to Q_t^i and Q_v^i in the partition function $Q = Q_t \Sigma Q_t^i Q_v^i g_i \exp(-c_2\epsilon_i/T)$. Uncertainty in the energy and molecular constants for the estimated states may contribute as much as 2–3 $cal·K^{-1}·mol^{-1}$ to $S°$ at 3000 K. The molecular constants have been corrected to the natural isotopic abundances.

to be the same as in BaF.[7, 11] The O–H stretching frequency, 3650 cm^{-1}, is estimated from the alkali hydroxide series. The bending frequency, 431 cm^{-1}, is estimated by assuming that the ratio of the bending force constant to the stretching force constant is 0.022, which is the average ratio found in the alkali metal monohydroxides by Acquista and Abramowitz.[11, 15]
